A TREATISE

ON THE

PRINCIPLES AND PRACTICE

OF

MEDICINE;

DESIGNED FOR THE USE OF

PRACTITIONERS AND STUDENTS OF MEDICINE.

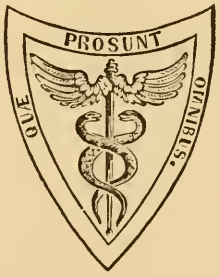
BY

AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE;
FELLOW OF THE NEW YORK ACADEMY OF MEDICINE;
HONORARY MEMBER OF THE MEDICAL SOCIETIES OF THE STATES OF VIRGINIA, RHODE ISLAND, KENTUCKY, AND MASSACHUSETTS;
ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA;
HONORARY FELLOW OF THE MEDICAL SOCIETY, AND OF THE CLINICAL SOCIETY OF LONDON;
CORRESPONDING MEMBER OF THE ACADEMY OF MEDICAL SCIENCE IN PALERMO, ETC.

FIFTH EDITION,

REVISED AND LARGELY RE-WRITTEN.



PHILADELPHIA:
HENRY C. LEA'S SON & CO.
1881.

Entered according to Act of Congress, in the year 1880, by
HENRY C. LEA'S SON & CO.
in the Office of the Librarian of Congress. All rights reserved.

COLLINS, PRINTER.

PREFACE.

In preparing the fifth edition of this treatise, the author has been thoroughly mindful of the progress of Medicine since the publication of the fourth edition in 1873. The treatise embraces in its scope General Pathology as well as Practical Medicine; and in each of these departments our knowledge has been in no inconsiderable degree advanced by zealous workers in different countries. The aim has been to bring the work, in all respects, up to the level of the present state of advancement in both the Principles and the Practice of Medicine. Time and effort have not been spared for this end.

The labor of the revision has been shared by Dr. William H. Welch, Lecturer on Pathological Histology in the Bellevue Hospital Medical College. Dr. Welch has contributed in Part I. the first seven chapters, embracing the general pathology of the solid tissues and of the blood. He has also revised, and in great part re-written, the descriptions of the anatomical characters of the diseases considered in the rest of the volume. It is believed that these portions of the work will serve as a digest of the essential facts pertaining to general and special pathological anatomy, as far as this important branch of study bears upon practical medicine.

In the other portions of the treatise will be found many changes which have somewhat enlarged the size of the volume, in spite of the omission of a considerable amount of matter, and the re-writing of many portions with a special view to condensation. Among these changes are, the introduction of a new section, devoted to the diseases of the hæmatopoietic system, the classification of the diseases of the nervous system on an anatomical, in place of a symptomatic, basis, a fuller consideration of various diseases, and the addition of several which were not considered in the previous editions. In the descriptions of individual diseases, larger space is accorded to the morbid anatomy, including histological appearances, and to the pathological character. In short, it may be claimed for the present edition that the eliminations, substitutions, and additions render it essentially a new work.

In making changes, the author has not been influenced by any sense of obligation to maintain consistency of views with the previous editions of this treatise, or with other works which he has written. Whenever statements are found to vary from those made at a prior date, the simple explanation is that the latter, in the light of more recent reflection and enlarged knowledge, seem to him no longer tenable. He has endeavored to regard his own writings, in this point of view, divested of the partiality of authorship, and to subject them to as critical an examination as if they were the writings of another.

Acknowledgments are due to Dr. Welch for valuable assistance in the revision of other parts of the work than those contributed by him, and in the task of proof-reading. The author also tenders his thanks to the present publishers for a continuance of the courtesy and kindness which rendered most agreeable his relations, for a quarter of a century, with their predecessors, Blanchard & Lea, and Henry C. Lea.

Repeating the language of the preface to the first edition, in submitting the fifth edition of the work to the judgment of his fellow-teachers and practitioners, "the author ventures to hope that it may be found to represent fairly the existing state of the science of medicine with respect to the subjects of which it treats, and to reflect the views of those who exemplify, in their practice, the present stage of the progress of medical art."

New York, December, 1880.

CONTENTS.

INTRODUCTORY CHAPTER.

PAGE

Scope of the term Medicine—Use of the term in contradistinction to Surgery and Obstetrics—Subdivisions of the different departments of Medicine, or specialties—The general object of this work—Meaning of the phrase Principles and Practice of Medicine—Definition of Pathology—Division into General and Special Pathology—Nomenclature of Diseases—Subdivisions of General Pathology, namely, Morbid anatomy including morbid changes of the fluids of the body; Etiology; Symptomatology; Diagnosis; Prognosis; Prophylaxis, and Therapeutics—Relations of these subdivisions to Special, as well as General, Pathology — Definition of Disease — Definition of Health—Relationship of Pathology to Physiology—Progress of pathological knowledge . . . 17

PART I.

PRINCIPLES OF MEDICINE, OR GENERAL PATHOLOGY.

CHAPTER I.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY.

Congenital Malformations—Local Anæmia—Hyperæmia—Hemorrhage—Diapedesis—Thrombosis and Embolism 25

CHAPTER II.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(Continued.)

Transudation—Dropsy—Exudation—Inflammation 33

CHAPTER III.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(Continued.)

Pathological New Formations — Regeneration — Hypertrophy — Tumors—Carcinoma 39

CHAPTER IV.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(Continued.)

Tubercle—Scrofula—Passive Alterations of the Tissues—Atrophy—Necrosis . 47

CHAPTER V.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(Concluded.)

PAGE

Infiltrations and Degenerations—Parenchymatous Degeneration—Fatty Metamorphosis—Mucoid and Colloid Degenerations—Amyloid or Waxy Degeneration—Calcareous Degeneration—Pigmentation 54

CHAPTER VI.

GENERAL PATHOLOGY OF THE BLOOD.

Plethora—Anæmia—Hydræmia—Anhydræmia—Hyperinosis—Hypinosis—Leucocytosis—Alterations in the gases of the Blood—Increase of Oxygen—Effects of breathing Compressed Air—Deficiency of Oxygen—Apnœa—Changes in the Albumen, Fat, and Inorganic Salts 60

CHAPTER VII.

GENERAL PATHOLOGY OF THE BLOOD—(Concluded.)

Glycohæmia—Acetonæmia—Uræmia—Ammoniæmia—Uricæmia or Lithæmia—Cholæmia—Cholesteræmia—Melanæmia—Septicæmia—Pyæmia . . . 73

CHAPTER VIII.

THE CAUSES OF DISEASE, OR ETIOLOGY.

Etiology a branch of General and Special Pathology—Its importance—Internal or Intrinsic and External or Extrinsic Causes—Ordinary and Special or Specific Causes—The terms Contagion, Infection, Miasm, Virus, Venom defined—Other poisons belonging to Toxicology—Traumatic Causes—Spontaneous Diseases—Primary and Secondary Causes—Complications and Intercurrent Diseases—Predisposing and Exciting Causes—Congenital and Inherited Predispositions to Disease—Co-operating or Accessory Causes—Diathesis—Cachexia or Dyscrasia—Endemic Diseases dependent on Emanations from the Soil—Epidemic Diseases produced by Causes existing in the Atmosphere—The Causes of Contagious Diseases exclusively derived from those affected with these Diseases—Fomites—Portability of the special Causes of Diseases not Contagious—The Causes of Contagious and Infectious Diseases probably Living Germs or Organisms—Animal and Vegetable Parasites . . . 87

CHAPTER IX.

SYMPTOMATOLOGY. DIAGNOSIS. PROGNOSIS.

Pathognomonic Symptoms—Diagnostic Symptoms—Subjective and Objective Symptoms—Signs—Clinical History of Diseases and the different Modes by which it is obtained—Stages of Disease—Precursory or Prodromic Events—Sequels—Diagnosis—Reasoning by way of exclusion—Differential Diagnosis—Prognosis—Prognostics 98

CHAPTER X.

PROPHYLAXIS—GENERAL THERAPEUTICS.

PAGE

Experience the Basis of Therapeutical Knowledge—Two Sources of Experience; Analysis of recorded Cases with reference to the Duration or Termination of Diseases, and Observation of the Immediate Effects of Therapeutical Measures —Rational Inference as a Means of arriving at Principles of Therapeutics— Importance of Knowing the Intrinsic Tendencies of Diseases toward Recovery, or otherwise—Active Measures to be employed only when clearly indicated— The Expectant Plan of Treatment—Conservative Medicine—Importance of Hygienic Measures of Treatment—Modes of Dying resolvable into Apnœa and Asthenia—Classification of Therapeutical Measures, according to the Objects to be accomplished, into Prophylactic, Abortive, Curative, Palliative, Hygienic and Sustaining Measures 109

PART II.

PRACTICE OF MEDICINE, OR SPECIAL PATHOLOGY.

INTRODUCTION.

Of the different aspects under which Individual Diseases are to be considered in treating of the Practice of Medicine or Special Pathology—namely, Anatomical Characters, Clinical History, Pathological Character, Causation, Diagnosis, Prognosis, Prevention, and Treatment—Sense of the Term Individual as applied to a Disease, and the several Grounds of Individuality—Varieties of a Disease—Definition of the Terms Acute, Subacute, and Chronic—Symptoms or Events incidental to Disease sometimes, for convenience, considered as Individual Diseases—Self-limited Duration of Certain Diseases—Nosology— Nosological Arrangement adopted in this Work 119

SECTION FIRST.

DISEASES AFFECTING THE RESPIRATORY SYSTEM.

CHAPTER I.

ACUTE PLEURITIS.

Division of the Diseases affecting the Respiratory System into Inflammatory and Non-inflammatory. Acute Pleuritis—Anatomical Characters—Clinical History —Pathological Character—Causation—Diagnosis—Prognosis 123

CHAPTER II.

ACUTE PLEURITIS—(CONTINUED.)

PAGE

Treatment of Acute Pleuritis—Measures indicated in the First Stage—General Considerations relating to Bloodletting in Acute Inflammations—The use of Opium in Acute Pleuritis and other Acute Inflammations—Measures indicated in the Second and Third Stages of Acute Pleuritis 133

CHAPTER III.

VARIETIES OF PLEURITIS.

Chronic Pleuritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Prognosis—Treatment. Thoracentesis. Suppurative Pleuritis, or Empyema—Diagnosis—Prognosis—Treatment. Pleuritis with Pneumothorax—Anatomical Characters—Clinical History—Diagnosis—Prognosis—Treatment. Pneumothorax. Circumscribed Pleuritis. Hydrothorax 140

CHAPTER IV.

PNEUMONITIS.

Seat of the Inflammation. Varieties. Acute Lobar Pneumonitis—Anatomical Characters—Laws of the Disease—Clinical History—Causation—Diagnosis—Prognosis 160

CHAPTER V.

TREATMENT OF ACUTE LOBAR PNEUMONITIS. VARIETIES OF PNEUMONITIS.

Treatment of Acute Lobar Pneumonitis—Pneumonitis in Young Children—Pathological Character of Acute Lobar Pneumonitis—Circumscribed Pneumonitis—Embolic Pneumonitis—Pyæmic Abscesses in the Lungs—Pigment, or Brown Induration—Pneumonokoniosis—Lobular Pneumonitis—Atelectasis—Pleurodynia and Intercostal Neuralgia—Hyperæmia of Lungs—Hypostatic Congestion—Hypostatic Pneumonitis 173

CHAPTER VI.

PULMONARY PHTHISIS.

Anatomical Characters—Clinical History—Pathological Character—Causation . 194

CHAPTER VII.

PULMONARY PHTHISIS—(CONTINUED.)

Diagnosis—Prognosis—Treatment 208

CHAPTER VIII.

FIBROID PHTHISIS. ACUTE MILIARY TUBERCULOSIS. GENERAL TUBERCULOSIS 223

CHAPTER IX.

BRONCHITIS.

Acute Bronchitis affecting the Large Bronchial Tubes—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis

PAGE

—Treatment. Subacute Bronchitis. Acute Bronchitis in Young Children. Bronchitis affecting the small Bronchial Tubes. Epidemic Bronchitis. Bronchitis with Fibrinous Exudation. Circumscribed Bronchitis. Chronic Bronchitis 227

CHAPTER X.

EMPHYSEMA OF THE LUNGS. ASTHMA. PERTUSSIS.

Emphysema of the Lungs. Interlobular or Interstitial Emphysema. Subpleural Emphysema. Vesicular Emphysema or Dilatation of the Air-cells—Senile Emphysema—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Asthma—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Pertussis, Whooping Cough 244

CHAPTER XI.

PULMONARY HEMORRHAGE. PULMONARY GANGRENE. PULMONARY ŒDEMA. CARCINOMA. HYDATIDS.

Pulmonary Hemorrhage. Broncorrhagia. Pneumorrhagia. Pulmonary Gangrene. Pulmonary Œdema. Carcinoma within the Chest. Hydatids . 269

CHAPTER XII.

DISEASES OF THE LARYNX AND TRACHEA.

Affections of the Larynx and Trachea. Points relating to the Anatomy and Physiology of the Larynx which are involved in the consideration of Diseases in this situation. Acute Simple Laryngitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute Laryngitis. Chronic Laryngitis. Laryngitis with Inflammatory Exudation—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Œdema of the Glottis. Spasm of the Glottis. Nervous Aphonia. Paralysis of the Laryngeal Muscles. Morbid Growths within the Larynx 285

SECTION SECOND.

DISEASES AFFECTING THE CIRCULATORY SYSTEM.

CHAPTER I.

PERICARDITIS.

Introductory Remarks. Pericarditis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Chronic Pericarditis. Pneumo-Pericarditis 311

CHAPTER II.

ENDOCARDITIS. MYOCARDITIS. ANEURISM OF HEART.

PAGE

Simple Endocarditis—Anatomical Characters — Clinical History — Pathological Character—Causation—Diagnosis—Prognosis — Treatment—Acute Ulcerative Endocarditis—Myocarditis 328

CHAPTER III.

VALVULAR LESIONS WITH ENLARGEMENT OF THE HEART.

Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment 333

CHAPTER IV.

HYPERTROPHY AND DILATATION OF THE HEART. ATROPHY, OBESITY, FATTY DEGENERATION. PARENCHYMATOUS DEGENERATION, AND THROMBOSIS OF THE HEART. EMBOLISM OF THE PULMONARY ARTERY 350

CHAPTER V.

FUNCTIONAL DISORDER OF THE HEART.

Enlargement of the Thyroid Body and Prominence of the Eye-balls (Exophthalmic Goitre) associated with Functional Disorders of the Heart. Angina Pectoris. Thoracic Aneurism 360

SECTION THIRD.

DISEASES AFFECTING THE HÆMATOPOIETIC SYSTEM.

CHAPTER I.

SIMPLE ANÆMIA. CHLOROSIS.

Introductory Remarks—Simple or Benign Anæmia—Chlorosis 374

CHAPTER II.

LEUCOCYTHÆMIA 380

CHAPTER III.

PSEUDO-LEUCOCYTHÆMIA. HODGKIN'S DISEASE . . 388

CHAPTER IV.

PERNICIOUS ANÆMIA 392

CHAPTER V.

ADDISON'S DISEASE 400

SECTION FOURTH.

DISEASES AFFECTING THE DIGESTIVE OR CHYLOPOIETIC SYSTEM.

CHAPTER I.

INFLAMMATORY DISEASES OF THE LARGE INTESTINE.

PAGE

Introductory Remarks. Anatomical Characters of Acute Dysentery. Sporadic Dysentery—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Epidemic Dysentery. Chronic Dysentery. Inflammation and Perforation of the Cæcum. Fecal Abscess. Inflammation and Perforation of the Vermiform Appendix. Colitis. Proctitis . . . 407

CHAPTER II.

INFLAMMATORY DISEASES OF THE SMALL INTESTINE AND OF THE STOMACH. PHARYNGITIS. PAROTIDITIS.

Acute Enteritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Enteritis. Acute Gastritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Gastritis. Phlegmonous Gastritis. Chronic Interstitial Gastritis. Duodenitis. Pharyngitis. Parotiditis 432

CHAPTER III.

STRUCTURAL AFFECTIONS OF THE STOMACH.

Softening. Gastric Ulcer. Carcinoma of Stomach. Dilatation of Stomach. Degeneration of the Gastric Tubes. Waxy Degeneration of the Stomach . 458

CHAPTER IV.

STRUCTURAL AFFECTIONS OF THE INTESTINE. INTESTINAL OBSTRUCTION.

Intestinal Ulcers—Duodenal Ulcer—Embolism of the Superior Mesenteric Artery—Carcinoma of the Intestines—Waxy Degeneration of the Intestines—Structural Lesions causing Intestinal Obstruction—Intussusception—Strangulated Hernia within the Abdomen—Rotation or twisting of Intestine—Compression and Stricture of the Intestine—Obstruction from Impaction of Feces, Enterolithes, and Foreign Bodies—Functional Obstruction 480

CHAPTER V.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE.

Acute Dyspepsia. Chronic Dyspepsia. Polyphagia, Malacia or Pica. Polydipsia, Dipsomania. Gastrorrhagia 499

CHAPTER VI.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE—(Continued.)

PAGE

Inanition. Gastralgia. Passage of Gall-stones. Diarrhœa. Enterorrhagia . 515

CHAPTER VII.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE—(Continued.)

Constipation. Intestinal Colic. Enteralgia. Lead Colic 532

CHAPTER VIII.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE—(Concluded.)

Sporadic Cholera—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Cholera Infantum. Epidemic Cholera—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Prevention—Treatment 546

CHAPTER IX.

INTESTINAL WORMS.

Ascaris Lumbricoides. Oxyuris Vermicularis. Tricocephalus Dispar. Ascaris Mystax. Tænia. Trichina Spiralis. Anchylostoma Duodenale . . . 568

CHAPTER X.

DISEASES OF THE PERITONEUM.

Acute Diffuse Peritonitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Treatment. Circumscribed Peritonitis. Chronic Peritonitis. Hydro-Peritoneum 581

CHAPTER XI.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN.

Suppurative Hepatitis. Chronic Interstitial Hepatitis (Cirrhosis). Acute Yellow Atrophy of the Liver. Syphilitic Hepatitis 602

CHAPTER XII.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN—(Continued.)

Fatty Liver. Waxy or Lardaceous Liver. Cancer of the Liver. Other New Growths in the Liver. Hydatid Tumors of the Liver. Parenchymatous Degeneration of the Liver. Pigmentary Deposit within the Liver. Hypertrophy of the Liver. Portal Thrombosis. Pyle-thrombosis. Adhesive and Suppurative Pyle-phlebitis 619

CHAPTER XIII.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN—(Concluded.)

Diseases affecting the Biliary Passages. Jaundice, or Icterus. Functional Affections of the Liver. Affections of the Spleen. Affections of the Pancreas 634

SECTION FIFTH.

DISEASES AFFECTING THE NERVOUS SYSTEM.

CHAPTER I.

DISEASES RELATING TO THE CEREBRAL AND THE SPINAL CIRCULATION.

PAGE

Cerebral Hyperæmia. Cerebral Anæmia. Cerebral Embolism and Thrombosis. Cerebral Hemorrhage. Localization of Cerebral Diseases. Meningeal Hemorrhage. Insolation or Sunstroke. Hyperæmia and Anæmia of the Spinal Cord and its Meninges. Spinal Hemorrhage 648

CHAPTER II.

INFLAMMATORY DISEASES OF THE MENINGES OF THE BRAIN AND OF THE SPINAL CORD. HYDROCEPHALUS. HYDRORRHACHIS.

Pachymeningitis and Hematoma of the Dura Mater—Acute Cerebral Meningitis—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Chronic Meningitis. Tuberculous Meningitis. Spinal Meningitis—Cerebro-spinal Meningitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Hydrocephalus. Hydrorrhachis 693

CHAPTER III.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE BRAIN.

Encephalitis. Inflammatory softening and Abscess of the Brain. Sclerosis of the Brain. Non-inflammatory Softening of the Brain. Intra-cranial Tumors. Chronic Bulbar Paralysis. General Cerebral Paralysis of the Insane . . 717

CHAPTER IV.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE SPINAL CORD.

Myelitis—Acute and Chronic. Cerebro-spinal Sclerosis. Locomotor Ataxia or Posterior Spinal Sclerosis. Anterior Poliomyelitis. Spinal Amyotrophic Affections. Acute Anterior Poliomyelitis. Acute Anterior Poliomyelitis in the Adult. Chronic Anterior Poliomyelitis. Progressive Muscular Atrophy. Progressive Unilateral Facial Atrophy. Spasmodic Spinal Paralysis. Amyotrophic Lateral Sclerosis. Compression of the Spinal Cord. Intra-spinal Tumors. Pseudo-hypertrophic or Myo-sclerotic Paralysis. Scleroderma . 732

CHAPTER V.

FUNCTIONAL DISEASES OF THE BRAIN AND SPINAL CORD.

Coma. Saturnine Encephalopathy. Vertigo and Ménière's Disease. Paralysis, remarks on. Treatment of Functional Paralysis. General Paralysis. Hemiplegia. Paraplegia. Acute Ascending Paralysis. Nervous Exhaustion or Neurasthenia. Spinal Irritation 764

CHAPTER VI.

DISEASES OF THE NERVES.

PAGE

Neuritis. Peripheral Paralysis. Paralysis of the Third Cranial Nerve. Paralysis of the Fourth Cranial Nerve. Paralysis of the Fifth Cranial Nerve. Paralysis of the Sixth Cranial Nerve. Paralysis of the Motor Portion of the Seventh Cranial Nerve. Paralysis of the Eighth Cranial Nerve. Paralysis of the Ninth Cranial Nerve. Local Paralysis of other than Cranial Nerves. Paralysis of the Cervical Sympathetic Nerves. Paralysis from Lead. Paralysis from Arsenic, Copper, and Mercury. Neuralgia. Trifacial Neuralgia. Cervico-Occipital Neuralgia. Cervico-brachial Neuralgia. Dorso-intercostal Neuralgia. Lumbo-abdominal Neuralgia. Crural Neuralgia. Sciatic Neuralgia. Dermalgia. Myalgia. Cephalalgia 781

CHAPTER VII.

THE NEUROSES.

Chorea. Anomalous Muscular Movements. Local Spasms. Tremor. Epilepsy 809

CHAPTER VIII.

THE NEUROSES—(Continued.)

Hysteria. Hystero-epilepsy. Catalepsy. Ecstasy. Somnambulism. Tetanus 832

CHAPTER IX.

THE NEUROSES—(Concluded.)

Rabies. Delirium Tremens, Alcoholism. Hypochondriasis, Pathophobia . 845

SECTION SIXTH.

DISEASES AFFECTING THE GENITO-URINARY SYSTEM.

CHAPTER I.

HYPERÆMIA AND ANÆMIA OF THE KIDNEYS. ACUTE AND CHRONIC BRIGHT'S DISEASE.

Active Congestion of the Kidneys. Passive Congestion of the Kidneys. Anæmia of the Kidneys. Parenchymatous Degeneration of the Kidneys. Fatty Degeneration of the Kidneys. Acute Bright's Disease. Chronic Bright's Disease 858

CHAPTER II.

ACUTE INTERSTITIAL OR SUPPURATIVE NEPHRITIS. DISEASES OF THE URINARY PASSAGES. PERINEPHRITIC ABSCESS.

Suppurative Nephritis and Pyelitis—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Hydronephrosis. Renal Colic and Nephro-Lithiasis. Perinephritic Abscess 895

CHAPTER III.

STRUCTURAL DISEASES OF THE KIDNEY. HÆMATURIA. HÆMOGLOBINURIA. DIABETES INSIPIDUS AND MELLITUS. SEXUAL DISORDERS.

PAGE

Renal Cysts. Cystic Degeneration of the Kidneys. Hydatids of the Kidney. Renal Tuberculosis. Carcinoma of the Kidneys. Movable Kidney. Renal Hæmaturia. Endemic Hæmaturia. Hæmoglobinuria. Diabetes Insipidus. Diabetes Mellitus — Clinical History — Causation — Diagnosis — Prognosis — Treatment. Involuntary Seminal Emissions. Spermatorrhœa. Impotence . 910

SECTION SEVENTH.

FEVERS AND OTHER GENERAL DISEASES.

CHAPTER I.

CLASSIFICATION AND PATHOLOGY OF FEVERS. CONTINUED FEVERS.

Classification of Fevers. The General Pathology of Fever. Febricula. Typhoid Fever—Anatomical Characters and Clinical History 942

CHAPTER II.

CONTINUED FEVERS—(Continued.)

Typhoid Fever, Continued—Causation—Diagnosis—Prognosis. Typhus Fever —Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis 960

CHAPTER III.

CONTINUED FEVERS—(Concluded.)

Treatment of Typhus and Typhoid Fever. Relapsing Fever—Anatomical Characters — Clinical History — Causation — Diagnosis—Prognosis—Treatment. Erysipelatous Fever. Epidemic Fever characterized by mild Erythematic Pharyngitis 974

CHAPTER IV.

PERIODICAL FEVERS.

Intermittent Fever—Anatomical Characters—Clinical History — Causation — Diagnosis—Prognosis—Treatment. Pernicious Intermittent Fever . . 994

CHAPTER V.

PERIODICAL FEVERS—(Concluded.)

Simple Remittent and Typho-malarial Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis — Treatment. Pernicious Remittent Fever. Yellow Fever — Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment 1010

CHAPTER VI.

ERUPTIVE FEVERS.

PAGE

Variola, or Smallpox—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Varioloid, or Modified Smallpox. Vaccinia, or Cowpox. Varicella, or Chicken-pox 1027

CHAPTER VII.

ERUPTIVE FEVERS—(Continued.)

Scarlatina, or Scarlet Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment 1051

CHAPTER VIII.

ERUPTIVE FEVERS—(Continued.)

Rubeola, or Measles—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Roseola. Rötheln. Dengue 1065

CHAPTER IX.

DIPHTHERIA.

Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment 1074

CHAPTER X.

ACUTE, SUBACUTE, AND CHRONIC ARTICULAR RHEUMATISM.

Acute Articular Rheumatism—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Articular Rheumatism 1089

CHAPTER XI.

GOUT. RHEUMATOID ARTHRITIS.

Gout—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Rheumatoid Arthritis . . 1102

CHAPTER XII.

SCORBUTUS. PURPURA HÆMORRHAGICA. HÆMATOPHILIA.

Scorbutus, or Scurvy—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Prevention—Treatment. Purpura Hæmorrhagica. Hæmatophilia 1118

THE

PRINCIPLES AND PRACTICE

OF

MEDICINE.

INTRODUCTORY CHAPTER.

Scope of the term Medicine—Use of the term in contradistinction to Surgery and Obstetrics—Subdivisions of the different departments of medicine, or specialties—The general object of this work—Meaning of the phrase Principles and Practice of Medicine—Definition of Pathology—Division into General and Special Pathology—Nomenclature of Diseases—Subdivisions of General Pathology, namely, Morbid anatomy including morbid changes of the fluids of the body; Etiology; Symptomatology; Diagnosis; Prognosis; Prophylaxis, and Therapeutics—Relations of these subdivisions to Special, as well as General, Pathology—Definition of Disease—Definition of Health—Relationship of Pathology to Physiology—Progress of pathological knowledge.

MEDICINE, in the largest sense of the term, comprehends everything pertaining to the knowledge and cure of disease. In a more restricted sense, the term is used in contradistinction to Surgery and Obstetrics. The latter are properly departments of medicine in the comprehensive sense of the term; and, although they may be cultivated separately, they cannot be disconnected from principles which are common to them and to medicine in its restricted sense. The medical profession embraces all who devote themselves to the study and practice of medicine proper, surgery, and obstetrics, either separately or combined. The physician is a member of the profession who devotes his attention to the diseases which belong to the department of medicine proper, *i. e.*, medicine in the restricted sense of the term. The physician may, or may not, undertake the duties which belong to surgery and obstetrics. In this country most physicians are, of necessity, to a greater or less extent, also surgeons and obstetricians, in other words, general practitioners. It is only in cities and large towns that practitioners can devote themselves exclusively, or chiefly, to surgery and obstetrics as separate departments of medicine. The distinction of physician, surgeon, and obstetrician, in this country, is purely conventional. The only degree conferred by our universities and medical colleges is that of Doctor of Medicine, which authorizes the practice of either or all the departments, and the same is true of licenses to practise medicine.

The division of medicine into the three departments which have been named is natural, and has contributed to the knowledge acquired in each department. Subdivisions have also been found convenient and useful. The latter are commonly known as specialties, and they who devote themselves to particular subdivisions are called specialists. The more important of the sub-

divisions now recognized as specialties are affections of the eye and ear, of the skin, of the genito-urinary system, diseases peculiar to females, orthopedic surgery, disorders of the mind and nervous system, diseases of the throat, nose, and larynx, and of the heart and lungs. Specialties result from an increase of knowledge rendering it difficult or impossible for one mind to compass all that has been ascertained in either of the three departments of medicine. The special cultivation of the several subdivisions of medicine leads to a further development of knowledge relating to each subdivision, and, hence, conduces to the progress of medicine. But, as the great principles of medicine are common to medicine proper, surgery, and obstetrics, so with regard to the subdivisions, they cannot be completely isolated from the departments to which they respectively belong. A particular class of affections cannot be studied satisfactorily to the entire exclusion of others, and without reference to the general laws of disease. Directing the attention exclusively to a specialty leads to the habit of attributing to it an undue relative prominence, and of regarding the diseases belonging to it as of paramount importance when they may be secondary or merely incidental to others which, from being overlooked or not sufficiently appreciated, fail to receive appropriate treatment. It is never advisable to pursue medical studies with exclusive reference to a specialty, nor to adopt one at the outset of medical practice.

The object of this work is to present the outlines of Medicine proper, that is, of medicine in contradistinction to Surgery and Obstetrics. *The Principles and Practice of Medicine* is a title of this department considered as a province of medical teaching. This title is here adopted in preference to others, such as the Theory and Practice of Physic, General and Special Pathology, Pathology and Practical Medicine, or the Science and Practice of Medicine. The principles and practice of medicine comprehend everything pertaining directly to the knowledge and cure of those diseases which the physician is called upon to treat. The province of medical teaching thus designated properly enough embraces the prevention of disease, and it may include anything which concerns the conduct of the physician in the treatment of patients affected with disease.

The study of disease, as a province of scientific knowledge, is called *Pathology.* This province consists of two important divisions, namely, *General* and *Special Pathology.* It is desirable to have a clear understanding of the terms which distinguish these two divisions of pathology. Diseases are presented in particular forms or species, constituting what are commonly known as individual diseases. The circumstances which give to the different diseases their individuality will be noticed hereafter. Now, the study of individual diseases constitutes special pathology. On the other hand, there are morbid conditions which are not peculiar to any individual disease, but are common to a greater or less number of diseases. The study of these conditions constitutes general pathology. Inflammation, for example, is a morbid condition which exists in a large number of individual diseases. The study of inflammation, as a condition common to different diseases, belongs to general pathology, while the study of the individual inflammatory diseases belongs to special pathology. To take another illustration: a morbid condition which enters into a number of individual diseases is called fever. In this sense of the term fever, it belongs to general pathology; but the study of the different forms of fever, or individual fevers, belongs to special pathology. The relation of general to special pathology is analogous to the relation of general to special anatomy, the former describing the several tissues which enter into the composition of the different organs of the body, and the latter describing the particular organs composed of the tissues. As the number of tissues is small in comparison with the number of organs, so the morbid conditions belonging

to general pathology are few as compared with the great number of diseases belonging to special pathology.

The province of medical teaching entitled the Principles and Practice of Medicine comprises both general and special pathology. The subjects which belong to the principles of medicine are derived from general pathology. The principles of medicine and general pathology are, in fact, synonymous terms, each term having the same scope of application. And, in like manner, the subjects which belong to the practice of medicine are derived from special pathology. These two terms relate to the same division of pathological knowledge, the former term being somewhat more comprehensive in its scope than the latter. The principles of medicine, thus, on the one hand, and the practice of medicine, on the other hand, constitute divisions which coincide with the two divisions of pathology distinguished as general and special. Moreover, these divisions are in accordance with the distinctions expressed by the terms Science and Art. "Science is knowledge reduced to principles; art is knowledge reduced to practice." The principles of medicine constitute medical science; the practice of medicine is the exercise of medical art. The object of this work being to present the outlines of both the principles and the practice of medicine, or of both general and special pathology, or, again, of medical science and art, it will be divided into two parts corresponding to these divisions. The outlines of the principles of medicine, or general pathology, will form the *First Part* of the work, and the *Second Part* will be devoted to the practice of medicine, or special pathology. In adopting this arrangement, however, I shall not be bound by it so closely as to treat of the topics belonging to general pathology exclusively in the first part of the work. It will be more convenient to defer the consideration of some of these topics, and to treat of them incidentally in connection with individual diseases. Moreover, I shall treat of general pathology in its relation to medicine, passing over, or noticing very briefly, those topics which are chiefly important in a surgical point of view. Although the general principles of pathology are common to both medicine and surgery, certain topics have relations especially to either the one or the other of these departments. The terms *medical pathology* and *surgical pathology* are used in conformity with this distinction.

The subjects of General Pathology, namely, the morbid conditions common to a greater or less number of individual diseases, are to be considered under various points of view; hence, this division of pathology admits of several subdivisions. One point of view relates to nomenclature, or the naming of diseases. The great desideratum in nomenclature, as applied to diseases, is, that the name of each disease shall express the morbid condition involved, and its situation. The names which were formerly applied to different forms of disease were frequently fanciful, and many of these are still in use, owing to the difficulty and inconvenience of displacing them after they have become established in medical literature; and in not a few instances it is by no means easy, with our existing knowledge of the essential character of morbid conditions, to substitute more appropriate names. Some approach, however, has been made toward a nomenclature which shall measurably secure the advantages derived from this source in other branches of knowledge, more especially in chemistry. The existence of inflammation, which enters into so large a number of individual diseases, is expressed by the suffix *itis* (ιτης) added to the anatomical name of the part affected. Thus, bronchitis, pneumonitis, pleuritis, peritonitis, etc., are names denoting the inflammatory character of the diseases to which they refer, and the particular structure which is the seat of the inflammation. The suffix *œa* (ῥεω) denotes the existence of the morbid condition known as transudation, or flux, occurring in a situation where the liquid escapes upon a mucous surface. Examples are

enterorrhœa, bronchorrhœa, gastrorrhœa, cystorrhœa, terms which have not, as yet, come sufficiently into vogue. The suffix *rhagia* (ῥηγνυμι) expresses a flow of blood, or hemorrhage from a mucous surface. Examples are metrorrhagia, gastrorrhagia (hæmatemesis), enterorrhagia (melæna), bronchorrhagia (hæmoptysis), in like manner terms which have not displaced others in common use. The suffix *algia* (ἀλγος) signifies a morbid condition characterized by pain without inflammation. Thus, neuralgia is a general term applied to this condition affecting any nerve or nerves; gastralgia, enteralgia, pleuralgia, etc., are terms severally expressing the neuralgic character of the affection and its seat. Words ending in *æmia* (ἁιμα) are applied to certain morbid conditions of the blood. Examples are anæmia (impoverishment of the blood), uræmia (morbid accumulations of urea in the blood), septicæmia (putrid infection of the blood), and pyæmia (purulent infection of the blood). Words ending in *uria* (ὁυρον) are applied to certain morbid conditions of the urine. Examples are albuminuria, hæmaturia, oxaluria. The prefix *hydro* (ὑδωρ) denotes a dropsical affection of the part named; as hydrothorax, hydrocephalus, hydro-peritoneum, hydro-pericardium. The prefix *pneumo* (πνευμα) denotes the presence of air in the part; as pneumothorax, pneumopericardium. The name of an inflammatory disease to which *peri* is prefixed signifies inflammation of the membrane investing the part inflamed, and the prefix *para* denotes inflammation of the surrounding connective tissue. Examples are perihepatitis, perinephritis, parametritis, etc. The suffix *pathy* (παθος) is used to express the fact of a morbid condition without indicating its character. Instances are arthropathy and encephalopathy. A termination in *oma* signifies a tumor, as sarcoma, carcinoma, myxoma.

It is thus seen that the effort to introduce names expressive of the character and seat of morbid conditions has, in a measure, succeeded. Further improvement in nomenclature will doubtless be made as our pathological knowledge increases.

An important subdivision of General Pathology relates to the appreciable morbid changes of the solids and fluids of the body. The study of all changes appreciable by the naked eye, or with the help of the microscope, constitutes a branch of pathology of great importance called morbid anatomy. Morbid anatomy is not confined to the study of the changes which occur in the tissues or solid parts; it embraces any changes which the eye can appreciate in the fluids of the body. The latter, not less than the former, are to be distinguished as anatomical, whereas those changes which are not visible either with the naked eye or by means of the microscope, but require for their detection processes of analysis or the employment of reagents, are usually considered as falling, not within the scope of morbid anatomy, but within the domain of animal chemistry. Morbid changes not visible, or not yet ascertained with our present means of observation, are distinguished as *functional*, and are also said to be *dynamic*. Doubtless in all the so-called functional or dynamic deviations from health there are either molecular or cellular, that is, anatomical changes, at present inappreciable, or, at all events undiscovered, which may be hereafter ascertained by continued investigation with improved means of observation. Appreciable anatomical changes are distinguished as *lesions*. The study of the minute anatomy of the tissues and fluids of the body with the microscope is called *Histology*, and the term *Morbid or Pathological Histology* is sometimes used to designate that part of morbid anatomy relating to those abnormal changes which are the objects of microscopical research. The study of the origin and development of pathological processes is called *pathogenesis*.

Anatomical changes, or lesions, belong to general pathology in so far as they are common to a greater or less number of individual diseases. Their

consideration, as involved in individual diseases, enters into special pathology or the practice of medicine. Such is the extent, as well as importance, of morbid anatomy, that it constitutes a distinct branch of medical knowledge. Treatises are specially devoted to it, and these are to be studied, in conjunction with the examination of morbid specimens, in order to become fully and practically acquainted with the various alterations in structure, form, size, etc., which are incident to disease. It is a fact, however, not to be lost sight of, that lesions do not constitute, but are the results of, disease. In other words, they are always due to underlying morbid actions or processes which may not be directly appreciable or well understood, but in which really consists the local disease. This fact, although obvious, is apt to be overlooked. Lesions are, of course, serious or otherwise, according to their character, their situation, and the amount of structural change involved. The plan of this work embraces, in *Part First*, the outlines of morbid anatomy in so far as it belongs to medical pathology, inclusive of known changes in the most important fluid of the body—the blood; and, in *Part Second*, a concise account of the lesions characterizing different individual diseases.

Another subdivision of General Pathology relates to the causation of disease. The study of the causes of disease is called *Etiology*. As belonging to general pathology or the principles of medicine, this branch of medical knowledge will be considered in *Part First* of the work; and the causes involved in the production of each of the individual diseases will be embraced in the account of the latter in *Part Second*.

The great number and variety of phenomena or events to which disease gives rise, constitute another subdivision of General Pathology. These phenomena or events are called symptoms, and their study constitutes a branch of medical knowledge called *Symptomatology or Semeiology*. Considerations relating to symptomatology, as belonging to general pathology, will claim attention in *Part First;* and the symptoms of individual diseases, respectively, forming, as they do, a highly important part of Special Pathology, or the practice of medicine, will be considered in *Part Second*.

Closely connected with symptomatology is another subdivision of General Pathology called *Diagnosis*. Diagnosis is the discrimination of diseases from each other. General considerations relating to this branch of medical knowledge will enter into *Part First*. In treating of individual diseases in *Part Second*, the means of discriminating them will be found to possess an importance second only to their treatment, and to be an essential prerequisite for the latter.

Another subdivision which will claim notice in both parts of this work is *Prognosis*, or the prediction of the termination of diseases.

The prevention of disease forms a branch of medical knowledge called *Prophylaxis*. This belongs alike to General and Special Pathology.

Lastly, the treatment of disease is called *Therapeutics*. General principles relating to the treatment of disease may be appropriately considered in connection with General Pathology. This portion of the subject is distinguished as *General Therapeutics*. I shall devote to it, together with prophylaxis, a chapter in *Part First*. It is hardly necessary to add that the treatment of individual diseases, distinguished as *Special Therapeutics*, is, in a practical view, the most important of the different aspects under which they are to be considered, being, in fact, the great end of both the principles and the practice of medicine.

It is thus seen that the subdivisions of General Pathology, which will be taken up in the first part of this work, represent also the different points of view under which individual diseases are to be considered in the second part of the work; that is, individual diseases, as well as the morbid conditions

common to a greater or less number of diseases, are to be considered with reference to the morbid changes either of solids or fluids which they may respectively involve, together with their causes, their symptoms, their discrimination or diagnosis, their prognosis, their prevention, and their treatment. Morbid anatomy, etiology, symptomatology, diagnosis, prognosis, prophylaxis, considered as branches of medical knowledge, belong to General Pathology, and to these may be added general therapeutics; and, on the other hand, Special Pathology, or the practice of medicine, considers the truths contained in these subdivisions of general pathology in their application to individual diseases.

Pathology has been defined the study of disease; but disease has not yet been defined. The definition of disease is confessedly difficult. It is easier to define it by negation, to say what it is not, than to give a positive definition, that is, a definition based either on the nature or essence of the thing defined, or on its distinctive attributes. Disease is an absence or deficiency of health; but this is only to transfer the difficulty, for the question at once arises, how is health to be defined? And to define health is not less difficult than to define disease. If all the tissues and organs of the body have their normal integrity and properties, if the fluids of the body be in no respect abnormal, if all the functions of the organism be completely and harmoniously performed, health undoubtedly exists. But this perfection of health is purely ideal; it never actually exists. An examination of the bodies of the healthiest persons would probably reveal lesions of some kind; certain deviations from the normal composition of the different fluids are not inconsistent with the evidences of health in other respects; functions of different parts may be disordered to a certain extent without sufficient disturbance to constitute disease. Gradations of health are implied in the qualifications of this term in common use. If the term health expressed a well-defined state, it would be a pleonasm to add to the term, as is often done, the adjectives good, excellent, etc.; and, on the other hand, to speak of health as poor, bad, miserable, etc., would involve a solecism. In short, health and disease are so imperceptibly merged into each other, that the line of demarcation cannot be drawn with precision And this is true of other departments of knowledge. It is not easy, for example, to settle upon the characters which mark the boundaries of the animal and the vegetable kingdom. But as there is rarely any practical embarrassment in distinguishing an animal from a vegetable, so with regard to health, if an important disease of any kind exist, the fact of its existence is in most cases sufficiently obvious. If, however, it be desirable to define disease otherwise than by saying that it is the absence or deficiency of health, the definition proposed by Chomel is, perhaps, as good as any other. According to this author, disease may be defined to be *a notable disorder affecting more or less of the constituent parts of the living organism, as regards either their material constitution or the exercise of their functions.*[1]

By regarding disease as the absence or deficiency of health, we are led to the consideration of the relationship of Pathology to Physiology. Physiology studies the operations which go on in the healthy organism. The morbid conditions which are the subject of pathological study are these operations disordered or perverted. Pathology has been called morbid physiology. Both are, in fact, parts of one science, the science of life, or biology. Both are alike occupied with vital properties, actions, and processes, the difference

[1] "Un désordre notable survenu, soit dans la disposition matérielle des parties constituentes, du corps vivant, soit dans l'exercise des fonctions." For an enumeration of the various definitions proposed by different writers, and some excellent remarks on the subject, this author may be consulted: Elémens de Pathologie Générale, quatrième édition.

being that physiology investigates them under the circumstances of health, and pathology under the circumstances of disease. The division is arbitrary, although sufficiently marked and appropriate.

Such being the relationship of pathology to physiology, it might be expected that the former would advance in proportion to the progress of the latter This is measurably true. While our knowledge of pathological conditions does not consist of deductions from what is known of the operations within the organism in health, but is derived from the direct study of disease, every important physiological discovery sheds more or less light on the department of pathology. In striving to penetrate into the nature of morbid conditions, it is evident that the chief difficulty arises from the imperfection of our knowledge of the properties, actions, and processes of health. There will be frequent occasions, in the progress of this work, to remark that the pathologist may expect to be better able to explain the phenomena of disease, when the physiologist has succeeded in elucidating more fully the phenomena of health.

In proceeding now to present the outlines of medicine, the aim of the author will be to give a truthful representation of pathological knowledge as it exists at the present moment. The progress of pathological knowledge has wrought, within late years, much change in both the principles and practice of medicine. Concerning further progress and its effects, it would be in vain to speculate; but it is not to be expected that a faithful exposition of medicine as it exists at the present moment will serve as a lasting guide for the student and practitioner. And in the study of medicine, next in importance to an acquaintance with what is actually known, is a just appreciation of the limits of our present knowledge. The latter is often important as regards its bearing on the treatment of disease, and it conduces to a condition of mind most favorable for either contributing to, or keeping pace with, the continued progress of knowledge.

PART I.

PRINCIPLES OF MEDICINE, OR GENERAL PATHOLOGY.

CHAPTER I.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY.

Congenital Malformations—Local Anæmia—Hyperæmia—Hemorrhage—Diapedesis—Thrombosis and Embolism.

A MULTIPLICITY of anomalies, occurring during intra-uterine life, are embraced under the name *congenital malformations.* They consist of either the malposition, the absence, or the incompleteness of organs, deficiency or redundancy as regards bulk, deviations of form, supernumerary parts, want of the normal connection between parts, etc. They may be due to intrinsic defects in the ovum, to arrested or obstructed development from various extrinsic causes, and in some instances they arise from the diseases to which the fœtus is liable. Passing by congenital malformations, this chapter will be devoted to certain definitions, distinctions, and general considerations relating to the changes in the solid parts, or lesions, which occur, as results of disease, after birth.

Anatomical changes in solid parts are recognized by means of morbid appearances, some of which are evident to the naked eye, and others require for their detection the microscope. The changes in color, form, etc., appreciable with the naked eye, constitute what are called the *gross or macroscopical*, and those discovered by the microscope are called the *microscopical appearances.* Certain changes are determined by the touch, namely, as regards softness or density, smoothness or roughness, alterations of form, etc. Increase and diminution in weight are also to be taken into account.

It is hardly necessary to add, but the fact is not always sufficiently considered, that the student must become familiar with the normal appearances (macroscopical and microscopical) of the different structures and organs of the body, before he is qualified to recognize and appreciate those which proceed from disease.

The subjects embraced in general pathological anatomy may be classified and considered under the following headings :—

1. Local disturbances of the circulation.
2. Active alterations of the solid tissues.
3. Passive alterations of the solid tissues.
4. General pathology of the blood.

The local disturbances of the circulation embrace *local anæmia*, *hyperæmia*, *hemorrhage*, *thrombosis* and *embolism*, *transudations*, and *inflammatory exudations.*

Local Anæmia.

Local *anæmia* or *ischæmia* signifies a deficiency of blood in a part. General anæmia or oligæmia will be considered in connection with the pathology of the blood. Local anæmia is due either to an increase of the resistance naturally offered to the flow of blood through a part, or to the presence of new obstacles within or outside of the vessel. Increase of the natural resistance is caused by contraction of the arteries in consequence of either direct stimulation of their muscular coat, or under vaso-motor influence. The pallor of the skin from the effects of cold, and that of the face at the onset of an epileptic paroxysm, or in consequence of violent emotions, are examples of local anæmia in consequence of spasm of the arteries. Atheroma, obliterating endarteritis, thrombosis, and embolism may be cited as causes of local anæmia acting within the vessels; compression of the arteries by tumors, exudations, bandages, illustrates the effect of external agents. As will be explained in treating of embolism and thrombosis, the presence or the absence of arterial anastomoses is of great importance in determining the degree of anæmia which follows the obstruction of an artery. By collateral anæmia is understood the diminution in the amount of blood in a part in consequence of its excessive accumulation in other parts. An anæmic part is generally pale, shrunken, dry, and, if exposed to the air, cool. The effects of long-continued and marked anæmia of a part are atrophy and frequently fatty degeneration. If the anæmia be extreme, coagulation-necrosis may result, as will be more fully explained subsequently.

Hyperæmia.

An increased amount of blood in the vessels of a part constitutes *hyperæmia*. Two forms of hyperæmia are recognized—*active* or *arterial*, and *passive* or *venous*. Active hyperæmia is also called fluxion. The term congestion is generally employed by English writers as a synonym for hyperæmia, although some understand by congestion only active hyperæmia. In active hyperæmia an increased amount of blood is brought to a part by the arteries. A gland or other organ is in a state of *functional hyperæmia* during its physiological activity. The usual cause of active hyperæmia is, in reality, a passive relaxation of the muscular coats of the arteries of a part, so that there results a diminution of the resistance naturally offered by the arterial tonus to the circulation of the blood. This relaxation may be the result of a direct paralysis of the muscular coat, but is usually referable to paralysis of the vaso-motor nerves. There is some reason to believe in the existence of vaso-dilator nerves, the irritation of which causes dilatation of the arteries and consequent hyperæmia.

Collateral or *compensatory hyperæmia* is the transmission of an increased amount of blood to a part in consequence of local anæmia of another, usually an adjacent, part. The sudden removal of long-continued pressure upon the arteries may be a cause of active hyperæmia, as, for instance, the over-distension of the abdominal vessels following rapid withdrawal of large accumulations of fluid in the peritoneal cavity. In active hyperæmia the velocity of the blood current is usually increased. The affected part is bright red in color, swollen, and, if superficial, warmer than normal. Active hyperæmia is usually an acute, transitory condition.

Passive hyperæmia is due to some obstruction to the flow of blood in the veins. From the nature of the obstruction it is also called mechanical hyperæmia, and venous hyperæmia inasmuch as it is venous blood which accumulates in the parts. Passive hyperæmia is frequently a chronic condition.

The abnormal hindrances may be either within or without the veins. Thrombi are the most frequent obstacles within the veins. General venous hyperæmia follows obstruction to the flow of blood through the heart. The veins may be compressed from without by clothing, bandages, tumors, exudations, newly formed fibrous tissue, etc.

By *hypostasis* or *hypostatic congestion* is understood venous hyperæmia of dependent parts of the body under the influence of gravity and of enfeebled heart's action. In most parts of the body the anastomoses between the veins are so many that a single vein, or even several, may be obstructed without serious disturbance of the circulation. Occlusion of the portal vein cannot be compensated for thus by collateral circulation. Venous hyperæmia of the lower extremity also follows thrombosis of the femoral vein. In passive hyperæmia the blood is dammed back upon the veins and capillaries of the part, the velocity of the circulation is lessened, the vessels become over-distended with blood, frequently a transudation of serum and a diapedesis of red blood corpuscles ensue, and an increased amount of lymph flows from the obstructed region. The affected part is usually bluish-red in color, swollen, frequently œdematous, and, if exposed to the air, cooler than normal. The diagnosis of hyperæmia cannot always be made upon post-mortem examination, as the distribution of blood may vary greatly from that present during life. This is particularly true of active hyperæmia.

Hemorrhage—Diapedesis.

Hemorrhage is the escape of blood through the walls of the vessels or of the heart. When the extravasation is through the ruptured wall of a vessel, it is called hemorrhage by *rhexis;* when the red blood corpuscles are pressed through the unruptured vascular wall, it is denominated hemorrhage by *diapedesis* or simply diapedesis. When the hemorrhages are minute, they are called *punctate* or *ecchymoses;* when the blood infiltrates the tissues uniformly without tearing them, the extravasation is a *hemorrhagic infarction;* when the escaped blood forms a tumor, it is called a *hæmatoma.*

According to the source of the blood, hemorrhages are classified as cardiac, arterial, capillary, and venous. The causes of hemorrhage by rhexis are various, and the consideration of many of them belongs to the domain of surgery. Rupture of healthy vascular walls is usually due to traumatism, or to local elevation of the blood pressure. Of the diseases which weaken the walls of the vessels and favor their rupture, the most important are aneurism, atheroma, ulcerative processes acting from without, infiltration of the vascular walls by new growths or inflammatory products, and perhaps fatty degeneration. Elevation of the general blood pressure, probably, never causes rupture of healthy vessels, but it may contribute to the giving way of those which are diseased.

Diapedesis occurs in venous hyperæmia, as already mentioned, in inflammation, and in hemorrhagic infarctions. It is due in venous hyperæmia to the increased intra-vascular tension, and in inflammation, as also, probably, in hemorrhagic infarctions, to changes in the vascular walls which are thereby rendered more permeable. The red blood corpuscles pass through the walls of the veins and especially of the capillaries, making their way between the endothelial cells, whether through preformed stomata, or not, is uncertain. Diapedesis is a passive process as far as the red corpuscles are concerned. Hemorrhages by diapedesis are generally small, but sometimes visible to the naked eye, and exceptionally they are considerable. It is not always possible to determine whether an extravasation is the result of rhexis or of diapedesis. A number of diseases are accompanied by a hemorrhagic tendency, such as

purpura, scurvy, phosphorus poisoning, and numerous infectious diseases, as septicæmia, yellow fever, smallpox, ulcerative endocarditis. The hemorrhage in these cases is doubtless due to a weakened condition of the vessel-walls in consequence of the disordered composition of the blood; but whether the blood escapes by rhexis or by diapedesis, has not been established in the majority of instances.

The changes which take place in a hemorrhagic extravasation lead to the gradual absorption of most of its constituents. The fluid parts are absorbed; the fibrin becomes granular and is taken up; the white blood corpuscles, in part, wander into the tissues and the absorbents, but, in greater part, disintegrate and are absorbed. Some of the red corpuscles are carried away by the lymphatics, others remain and undergo pigmentary transformations. The formation of pigment takes place, in great part, in wandering cells which take up the corpuscles or fragments of them. The resulting granular and crystalline hæmatoidin pigment may remain in the cells or be set free. Thus only pigment may remain to tell of the former extravasation, and even this pigment may be in time absorbed. These changes may be complicated by acute and chronic inflammatory processes. The formation of so-called apoplectic cysts in the brain will be described when treating of cerebral hemorrhage.

Thrombosis and Embolism.

A coagulum formed during life in the heart or in the vessels is called a *thrombus*. A thrombus is designated as *parietal* when it is attached to the wall of a vessel which it only partially obstructs. An *occluding* thrombus completely fills the interior of the vessel. The causes of thrombosis are, *first*, changes in the walls of the vessels, and, *second*, retardation of the circulation. Of the alterations in the vascular wall which cause thrombosis, the most important affect the endothelial lining, the integrity of which is believed to be an essential condition of the fluidity of the blood, and the greater number produce irregularities upon the inner surface of the vessel. The leading structural changes are incident to acute and chronic inflammations (embracing atheroma and endocarditis), calcification, degeneration of the endothelium, and new growths. *Compression-thrombosis*, which results from narrowing of the vessel by external pressure, belongs to this group of causes. Here also should be included *traumatic thrombi* which form in wounds of the vessels. The *dilatation* thrombi and the *marantic* thrombi are the most important of those caused by retardation of the circulation. The former are produced in consequence of abnormal dilatation of the vascular channels, as in aneurisms and in varices. Marantic thrombi are the result of great weakening of the circulation, such as comes from extreme debility and from much enfeebled heart's action. The veins of the lower extremities and of the pelvis, and, in children, the cerebral sinuses, are the favorite seats of marantic thrombi. In many instances, as, for example, in thrombosis following ligature of a vessel, structural alterations and slow circulation combine as causes of thrombosis. Primary venous thrombi form especially in the pockets of the valves, cardiac thrombi in the right auricular appendix and in the apex of the right ventricle. A thrombus extends at least from the point of its formation to the nearest branch given off from the vessel; it may extend further forward and backward, and may grow into the collateral branches.

Thrombi vary in structure according to their formation from the blood while in motion, or at rest. *White*, *red*, and *mixed* thrombi are thus distinguished. Red thrombi are formed from blood at rest, as, for instance, in a vessel inclosed between two ligatures, and are composed of red and white corpuscles and fibrin, the coagulum being similar to that of blood withdrawn

from the body. White thrombi are really grayish or reddish-gray in color, and are composed chiefly of white corpuscles and fibrin. They are formed from the circulating blood, and are produced by an accumulation of white blood-corpuscles, as has been experimentally demonstrated by Zahn.[1] The white corpuscles subsequently lose their nuclei, seem to coalesce with each other, and produce a granular material with the properties of fibrin. Some corpuscles usually remain intact in the granular mass. Generally some red corpuscles are entangled among the white. Mixed thrombi constitute a variety of the white. They are composed usually of different layers, some white and some red. The great majority of all thrombi are white or mixed. A thrombus is more or less firmly adherent to the wall of the vessel. It presents, as a rule, a distinctly stratified appearance. It is, of course, of great importance to be able to distinguish between thrombi and post-mortem coagula. The latter may be dark red in color or yellowish-white. It is the yellowish-white, so-called decolorized post-mortem clots which have been most frequently mistaken for ante-mortem thrombi. Those so often found in the right cavities of the heart, with prolongations extending into the branches of the pulmonary artery, have been erroneously assigned as the cause of death. These light-colored clots are produced when the coagulum forms so slowly that the corpuscular elements, particularly the heavy red blood-corpuscles, have time to sink to the bottom, so that the upper portion of the coagulum consists almost wholly of fibrin with some white corpuscles. The light post-mortem clots therefore consist of a lower red cruor-mass and an upper whitish fibrinous material; they are not intimately adherent to the vascular wall; they have a gelatinous, translucent appearance, and are not distinctly stratified. The ante-mortem thrombi may consist of red and gray layers, but these are irregularly arranged; they are opaque, granular in appearance, distinctly stratified, and adherent to the wall of the vessel.

A thrombus may remain for a long time without much change, or it may undergo metamorphosis in one of two directions, either *organization* or *softening*. The so-called organization of a thrombus results in the formation of vascularized connective tissue in the place of the thrombus. All of the details of the process are not understood, but it is now generally admitted that the thrombus itself gradually breaks down and disappears without taking part in the formation of the new tissue. The process seems to be essentially an obliterating endarteritis, the new connective tissue cells being derived either by proliferation from the endothelium of the thrombosed vessel, or from wandering cells escaped by emigration from the vasa vasorum or the surrounding tissues. The new vessels are offshoots from the vasa vasorum. By retraction of the new connective tissue, or by peculiarities in the process of organization, canals may be formed which connect the interior of the vessel on the peripheral side of the thrombus with that on the central side. By this so-called *canalization* of the thrombus, the circulation may be re-established nearly in its old channels, but this termination is infrequent. Instead of organizing, a thrombus may break down in its central portion into a grayish-red pulp consisting of granular material with some blood-corpuscles and blood-pigment. This detritus was formerly mistaken for pus. The process is called *simple or puriform softening*. In this way some thrombi, especially globular thrombi in the heart, may resemble cysts with fluid contents. A different and more serious form of softening is that which occurs in thrombi containing some infectious principle. From a clinical, as well as a pathological, standpoint, it is important to distinguish between *non-infectious or bland thrombi*, and *infectious* thrombi. While the former undergo organization, the latter

[1] Zahn, Virchow's Archiv, Bd. 62, 1875.

break down into a diffluent mass composed of granular material, bacteria, pus-cells, and red corpuscles or their fragments. Portions of this softened material entering the circulation form a fruitful source of general infection. These infectious thrombi form in diseases characterized by blood-poisoning, such as pyæmia, acute ulcerative endocarditis, puerperal fever, etc. Sometimes the thrombi in varices become impregnated with the salts of lime and form concretions called phleboliths.

The effects and symptoms of thrombosis, in the first place, depend upon the *mechanical obstruction* to the circulation. The degree of this obstruction depends upon the situation and the extent of the thrombus. A parietal thrombus may produce so little obstruction as to give rise to no symptoms. Completely occluding thrombi produce no mechanical hindrance when lodged in vessels provided with anastomoses which afford a sufficient collateral circulation. Thus a thrombus in one of the venæ comites of an artery, forms no apparent obstacle to the circulation. On the other hand, thrombosis of the portal vein (pyle-thrombosis) or of the femoral vein (phlegmasia alba dolens), is followed by well-marked symptoms of venous obstruction. These symptoms of venous thrombosis are passive hyperæmia with more or less transudation of serum and diapedesis. The mechanical effects of arterial thrombi are anæmia of the part supplied by the artery, and necrosis or hemorrhagic infarction. These effects are usually absent when the thrombus is seated in an artery the branches of which communicate freely by anastomosis. As these mechanical effects of arterial thrombi are the same as those of emboli, they will be more fully considered presently while treating of the latter. On account of their slow formation, a sufficient collateral circulation may be developed to render thrombi comparatively harmless in situations where emboli produce their characteristic effects. Independently of their mechanical action, thrombi may be injurious by containing some irritative infectious principle. The infectious thrombi cause suppuration and sometimes necrosis in the vascular wall and the tissues where they are lodged.

A special danger attendant upon thrombosis, is the detachment of portions of thrombi and their transportation by the circulation into smaller vessels which they obstruct. These severed fragments of thrombi, or even entire thrombi, which enter the circulation, are called *emboli*. An embolus is a plug of some material which is transported by the blood-current from one situation to another. An embolus may consist of any substance which makes its way into the current of blood. The majority of emboli are fibrinous, being derived from thrombi. But emboli may consist also of portions of a tumor growing within a vessel, of fragments of diseased cardiac valves, of animal and vegetable parasites, of concretions of lime, of pigment, of fat, or of bubbles of air. It is plain that a migratory plug or an embolus can hardly be arrested in its course through the veins (with the exception of the vena portæ), since the course of the blood-current in them is from smaller to larger vessels. Embolism, therefore, relates to the arteries, with the single exception of the vena portæ, while a thrombus may be formed anywhere in the vascular tract. A parietal thrombus may be washed off partially or completely by the blood flowing over it. The thrombi or so-called vegetations formed on the cardiac valves in endocarditis, are a fruitful source of emboli. An end of a thrombus may be broken off by the force of the current from a vessel over the mouth of which the thrombus projects. Finally, fragments may be detached from thrombi in consequence of softening. Emboli consisting of oil-globules enter the circulation most frequently after fracture of the bones, particularly when accompanied by extensive laceration of the marrow. Fat set free from marrow-cells enters the open mouths of ruptured veins. The oil-drops collect chiefly in the pulmonary capillaries, where they can be recognized only by

the microscope. They may pass through these capillaries and lodge in the glomeruli of the kidneys, in the cerebral capillaries, and in other capillaries of the body. In most cases emboli of fat are innocuous. They may, however, occlude a sufficient number of pulmonary capillaries to occasion severe symptoms or even death, especially when the patient is already much prostrated. An excretion of fat by the kidneys has been noticed two or three days after comminuted fractures. Fatty emboli may proceed from rupture of the liver, and from fatty metamorphosis of abscesses and of thrombi. The sudden entrance of a large quantity of air into the blood-current, such as may occur by incision of the large veins near the heart, has been long known as a cause of rapid death. The fatal termination is due to the accumulation of the air in the right cavities of the heart, the contraction of which is unable to force the elastic air forward. The air remaining in the right auricle and ventricle forms an obstacle to the entrance of blood from the venæ cavæ, and arrests the pulmonary and systemic circulation.

Of especial interest and importance is the study of the mechanical effects of emboli. While all arteries of the body are open for the reception of emboli, it is noteworthy that in certain situations the obstruction of an artery by an embolus is absolutely harmless, whereas, in other parts it is followed by characteristic structural and functional alterations. The main condition upon which this difference depends is the character of the arterial distribution in the various parts of the body. In certain organs and parts of the body, the branches of the arteries do not anastomose with each other, communications existing only between the capillaries and between the veins. These arteries without anastamoses are called by Cohnheim terminal arteries (*Endarterien*). Such arteries are the renal, splenic, pulmonary, certain of the cerebral, and the central artery of the retina. The branches of the vena portæ also do not enter into anastomosis with each other. When an embolus lodges in an artery supplied with abundant anastomoses, for instance a muscular artery or one of the arteries of the extremities, a collateral circulation is established, which prevents the part from suffering in its nutrition or function. The effect is widely different if no anastomoses exist between the peripheral part of the occluded artery and other vessels. Now no arterial blood or an insufficient amount is sent to the capillaries of the part supplied by the artery. The part suffers in its nutrition, and may even undergo necrosis or death. An extravasation of blood sometimes, but not necessarily, supervenes in the district the arterial blood-supply of which has been cut off. These alterations constitute *embolic infarctions* which are therefore of two kinds—*white* or *anæmic infarctions* and *hemorrhagic infarctions*.[1] An embolus produces a white infarction when its effect is anæmia and necrosis without hemorrhage. Anæmic infarctions are to be distinguished from decolorized hemorrhagic infarctions, with which they were formerly confounded. The primary and essential change in most white infarctions is coagulation-necrosis, a process by which the cells lose their nuclei and change their chemical composition. The details of this peculiar metamorphosis will be described under the passive alterations of the tissues.

There have been various theories as to the source of the extravasated blood in hemorrhagic infarctions. The explanation advanced by Cohnheim and derived from microscopical observation of the process in the tongue of the living frog, has been generally received.[2] Occlusion by an embolus or by ligature of terminal arteries in the frog's tongue is followed by cessation of the circulation on the peripheral side of the obstruction. Stasis occurs in the vessels in the district the artery of which is closed. The circulation goes on

[1] The term infarction is, strictly speaking, only applicable to the hemorrhagic form.
[2] Cohnheim, Untersuchungen über die embolischen Processe, Berlin, 1872.

even with increased vigor in the surrounding vessels. The blood-pressure on the peripheral side of the obstruction being reduced to nothing, the blood flows back from the veins which connect with the capillaries, the arterial supply of which is shut off. These veins receive their blood from surrounding veins from which the current has not been cut off. The capillaries of the obstructed district become filled with blood which has regurgitated from the veins. The walls of these capillaries and small veins, not receiving a fresh supply of arterial blood, finally become weakened and allow a diapedesis of the red corpuscles. In this way Cohnheim explains the formation of embolic hemorrhagic infarctions. Recent experiments of Litten,[1] however, seem to show that the extravasated blood, at least in some cases, is derived, not by return flow from the veins, but from the adjoining capillaries and small arterial anastomoses in which the pressure suffices to send the blood into the capillaries of the part whose artery is occluded, but not onward into the veins. Litten also maintains that many of Cohnheim's terminal arteries are such only in an anatomical, not in a functional, sense; that is, when they are occluded, blood may still reach their capillaries from surrounding capillaries and small arterial twigs, although the amount of blood may not suffice for the nutrition of the part.

The seats of embolic infarction are the kidneys, spleen, brain, lungs, retina, and, under certain circumstances, the liver and small intestines, very rarely other parts of the body. In the kidneys embolic infarctions are more frequently white than hemorrhagic; in the spleen both occur, but the hemorrhagic with greater frequency. In certain parts of the brain simple anæmic softening with or without hemorrhage follows embolism; embolism of a branch of the pulmonary artery is often without any effect, at other times, especially in the periphery of the lung, a hemorrhagic infarction results. Occlusion of the main trunk of the superior mesenteric artery is followed by hemorrhage in the wall of the small intestine; emboli in branches of the portal vein do not usually produce infarctions, as the hepatic artery can supply the lobular capillaries. Why in some cases an infarction is simply necrotic, in others also hemorrhagic, is not always clear. It depends especially, according to Cohnheim, upon the ease with which the blood can flow back from the veins, and this is dependent on the pressure in the veins, and the presence or the absence of valves. The special characters of embolic infarctions in different organs will be considered under the diseases of these organs in Part II. of this work. Infarctions are generally wedge-shaped (not so in the brain), corresponding to the area of distribution of the obstructed artery. The base of the wedge is toward the periphery of the organ. A hyperæmic zone containing numerous emigrated white blood-corpuscles is usually found around the borders of the infarction. A reactive inflammation ensues in the periphery, resulting in the formation of new connective tissue which gradually takes the place of the infarction, many of the constituents of the latter being absorbed. The infarctions lose their dark red color and become yellowish. The termination is in a cicatrix of fibrous tissue, which often contains pigment when the infarction was hemorrhagic.

The presence of disease of the arteries and an enfeebled circulation may be important factors in determining the effects of an embolus. Thus, embolism of the femoral artery produces no permanent injury when the force of the circulation is normal and the anastomosing arteries healthy; but it may be followed by gangrene of the lower extremity if the heart's action be feeble and the arteries atheromatous. So, too, a number of emboli in the arteries of a part may occasion severe trouble, where a single embolus would be innocuous. Embolism of the main trunk of the pulmonary artery, or of

[1] Litten, Studien über den hämorrhagischen Infarct, Berlin, 1879.

certain arteries of the medulla oblongata, causes sudden death. In certain situations, and under certain circumstances, the ischæmia or local anæmia caused by an embolus is of short duration. Thus, a temporary loss of function disappears when the vessels beyond the seat of obstruction are filled by collateral arterial branches.

The preceding remarks have been made with reference to bland or non-irritating emboli. Infectious emboli, such as come from the cardiac valves in acute ulcerative endocarditis and from infected thrombi, produce effects entirely distinct from the mechanical obstruction to the circulation. They incite suppurative inflammation, and perhaps necrosis, wherever they lodge. Thus, even capillary emboli, when infectious, produce abscesses. The multiple abscesses in pyæmia are, for the most part, of embolic origin. Bacteria are generally to be found in infectious emboli, and, in some cases at least, constitute the poisonous principle.

In conclusion, it may be mentioned that Ponfick[1] has demonstrated that hard emboli, such as those impregnated with the salts of lime, may produce aneurisms by penetrating the intima of small arteries in parts offering little resistance, for example the brain or the mesentery.

CHAPTER II.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(CONTINUED.)

Transudation—Dropsy—Exudation—Inflammation.

Transudation—Dropsy.

TRANSUDATION is the filtration of a fluid resembling the serum of the blood through the capillary walls. A distinction is made between a *transudation* and an *exudation*. An exudation is inflammatory in its origin, a transudation is non-inflammatory; an exudation is usually richer in albumen and white blood-corpuscles than a transudation, and is distinguished especially by the presence of coagulated fibrin. But both transudations and exudations vary greatly in their composition, and it is impossible to draw a sharp line of distinction between them. In fact, the two terms are often used synonymously.

Transudations may take place in different situations. Occurring in situations from which the liquid cannot escape, namely, within serous cavities and into the tissues, they constitute *dropsies*. Occurring upon mucous surfaces they form one variety of *fluxes*. Dropsies receive different names according to their situation. In serous cavities they are designated by prefixing *hydro* to the name of the membrane affected; thus, hydrothorax, hydropericardium, hydroperitoneum or ascites, and hydrocephalus. Hydrocele is a serous accumulation in the tunica vaginalis testis. Serous transudation into the tissues, particularly into the interstices of connective tissue, is called *œdema*. When subcutaneous œdema extends over the greater part of the

[1] Ponfick, Virchow's Archiv, Bd. 58, p. 528.

body, it receives the name *anasarca.* Serous effusion into the pulmonary air-cells is called *œdema of the lungs*, contrary to the usual signification of œdema. The term *hydrops* signifies a serous effusion, usually in a cavity. Accumulations of serous fluid in glands and canals, the outlets of which are obstructed—for example, in the Fallopian tube (hydrops tubæ), in the gall-bladder (hydrops felleæ)—are to be distinguished from real dropsical effusions, although the composition of the fluids may be similar.

Dropsical effusions are generally clear, colorless or slightly yellow, and alkaline in reaction. They may be stained by an admixture of blood or of biliary coloring matter. They contain the same salts as the serum of the blood, and in about the same proportion. The amount of albumen varies between 0.4 and 5 per cent., being less than that present in the blood-plasma. Transudations into the pleural and peritoneal sacs are richer in albumen than those in the subcutaneous tissue, while the transudations in the subarachnoid space contain the least proportion. Most transudations contain fibrinogen, one of the fibrin-generators. According to Schmidt's theory, fibrin is not contained as such in the blood, but is formed by the union of the two fibrin-generators, namely, the fibrinogenous and the fibrinoplastic substance, in the presence of the so-called fibrin-ferment. The fibrinogenous substance is contained in solution in the blood-plasma, but the fibrin-ferment and, in part, the fibrinoplastic substance are formed by the disintegration of white blood-corpuscles and, probably, of other cells. Fibrinogen is abundant in the fluid of the pericardium and of hydrocele. Transudations in the living body very rarely contain fibrin, but after death fibrin may be formed in consequence of the liberation of the ferment and of fibrinoplastin by disintegration of cells. Many transudations coagulate spontaneously when withdrawn from the body. This may be explained, at least in many cases, by the admixture of blood in the withdrawal of the liquid, for it has been demonstrated that the addition even of a small amount of blood will cause often an abundant coagulation of fibrin in dropsical effusions. According to Hammarsten,[1] fibrin may be formed from fibrinogen in the presence of the ferment without the addition of the fibrinoplastic substance or paraglobulin as it is also called. In rare instances, transudations in the pleural and in the peritoneal cavities have been rendered milky in appearance by an admixture of chyle derived from the chyle-vessels, particularly the thoracic duct, in consequence of their occlusion or rupture. Such a transudation is called *hydrops chylosus.* Examined microscopically, transudations are found to contain a few leucocytes and some red blood-corpuscles, the latter occasionally in abundance.

Under normal conditions there is a serous transudation, called the lymph, from the blood. It is natural to suppose that hindrances to the outflow of lymph by obstacles in the lymphatic vessels, would cause an abnormal accumulation of lymph in the tissues and serous sacs. But it has been found that, not only the peripheral lymphatics, but even the thoracic duct may be completely occluded without producing local or general dropsy. The lymph does not accumulate under these circumstances for the reason that the blood-vessels act as absorbents when the lymphatics are occluded, and because relief is afforded by collateral lymphatic channels. Still, it is not to be doubted that obstacles to absorption increase the efficacy of the causes of dropsy. These efficient causes are, *first*, hindrances to the outflow of blood through the veins, causing venous hyperæmia; *second*, alterations in the walls of the blood-vessels, especially those induced by hydræmia. Dropsies due to the first of these causes are called *mechanical;* those due to hydræmia are called *cachectic* or *hydræmic.* Diseases of the heart or of the lungs, which impede the

[1] Hammarsten, Ueber das Paraglobulin, Pflüger's Archiv, xvii. and xviii.

return-flow of blood from the venæ cavæ, produce general dropsy when the hindrance is sufficiently great. General dropsy is characterized by anasarca and transudations into the serous sacs. The most frequent and important of the mechanical causes of general dropsy is cardiac disease. The mechanical causes of local dropsy are those of venous hyperæmia, which have already been mentioned. The most important of the local dropsies is hydro-peritoneum or ascites dependent upon obstruction of the vena portæ. Thrombosis of the portal vein (pyle-thrombosis) and certain hepatic diseases, especially cirrhosis, cause portal obstruction with ascites.

It is noteworthy, that, while venous hyperæmia, which is attended by increased blood pressure and retardation of the circulation, is followed by dropsy, simple, active hyperæmia, which is accompanied by increased pressure and velocity of the blood-current, does not lead to increased transudation. General dropsy, due to a morbid condition of the blood, in the majority of cases is connected with those affections of the kidney embraced under the name Bright's disease. The hydræmia, which results from the excretion of albumen by the urine in this disease, is not the immediate cause of the dropsy, but it induces in the vascular walls a change which renders them more permeable. That hydræmia is, not an immediate but an indirect, cause of dropsy, has been demonstrated by the experiments of Cohnheim and Litten,[1] who found that when the vascular walls are healthy, large quantities of dilute solution of common salt can be injected into the vessels of animals without causing increased transudation in the situations in which dropsy occurs in man. Other cachexiæ, especially the cancerous and the tuberculous, may be attended by hydræmic dropsy, although this is usually less in degree than that of Bright's disease. Some effusions, which have been regarded as dropsical, are really inflammatory in their origin, that is, due to an inflammatory alteration in the coats of the vessels. This is usually true of the so-called collateral œdema, that is, the œdema in the neighborhood of inflammatory infiltrations, tumors, etc. It is also true of œdema glottidis, and many cases of hydrocele and hydrocephalus.

Exudation—Inflammation.

The distinctions between an exudation and a transudation have been already mentioned, as well as the difficulty of enforcing them in all cases. The leading characteristic of an exudation is, that it is a product of inflammation, a process to be considered in this connection.

According to the classical definition of inflammation, a part is acutely inflamed when it is hot, red, swollen, and painful. But this enumeration of the four cardinal symptoms (calor, rubor, tumor, dolor) gives no information as to the pathological nature of the process. No topic in medicine has been the subject of so much research and speculation as the nature of inflammation, but, even at the present time, it is impossible to give a complete and correct definition of inflammation from a pathological or an etiological standpoint. From the earliest times two opposing theories regarding the process of inflammation have been maintained. According to the one, the essential phenomena in inflammation are referable to the blood and to the bloodvessels; according to the other, the essential changes are in the solid tissues outside of the bloodvessels. A great advocate of the former theory was John Hunter. Recently it has been developed especially by Cohnheim. Virchow, on the other hand, rejecting the Hunterian doctrine, maintained that the primary and chief effect of an inflammatory irritant is the excitation of the cells of a part to

[1] Cohnheim und Litten, Virchow's Archiv, Bd. 69, 1877.

increased functional and nutritive activity, and that hyperæmia and fluid exudation from the blood are secondary to this excitation. When Virchow made his researches on inflammation, nothing was generally known concerning the emigration of white blood-corpuscles or their wandering powers, and he naturally concluded, in the application of the law *omnis cellula e cellula*, that all cell-elements present in inflammatory exudations were produced by proliferation from the pre-existing fixed cells, most frequently from the connective-tissue cells. The discovery by Recklinghausen, in 1863, of the existence of wandering cells, resembling pus-cells, in the tissues, rendered doubtful the interpretation which Virchow had given to many of his observations. A new era was introduced in the history of inflammation by Cohnheim's discovery, in 1867, of the emigration of white blood-corpuscles from the vessels, and by his studies of the inflammatory process on living frogs. It is true that, as long ago as 1846, Waller, an English observer, saw the passage of white blood-corpuscles through the unruptured vessel-walls, but this isolated observation had remained fruitless, and had fallen into forgetfulness when Cohnheim repeated the discovery.

The phenomena of inflammation were observed first by Cohnheim, microscopically, upon the mesentery and tongue of the curarized frog. The first effect of the application of an inflammatory irritant (the mere exposure of the mesentery to the air suffices) is a dilatation of the arteries, then of the veins, and, least of all, of the capillaries. At the same time the velocity of the blood-current is increased. After a variable time, the blood begins to flow less rapidly, although the calibre of the vessels remains unchanged. In some of the capillaries it may come to complete stagnation or stasis, but this is not essential, nor usual except when the action of the irritant is intense. As the rapidity of the blood-current lessens, the white blood-corpuscles accumulate along the inner surface of the veins, where they remain nearly stationary. The remarkable phenomenon of emigration now takes place. A portion of a white blood-corpuscle soon appears upon the outer surface of a vein or a capillary, as a bud-like process connected by a delicate thread of protoplasm with the remnant of the corpuscle inside. As the outer portion of the cell increases in size, the inner diminishes, until, finally, the entire corpuscle lies free outside of the vessel. The corpuscle passes through the cement-substance between the endothelial cells lining the vessel. The evidence is not conclusive that it passes through preformed stomata or pores. Nor is it certain whether the corpuscles make their way through the vascular walls by their active amœboid movements, as the name emigration would imply, or whether they are pressed through by a passive process of filtration. Outside of the vessels they assume amœboid movements and change their shape and place. While the inner surface of the veins becomes plastered, as it were, with stationary white blood-corpuscles, the current of red blood-corpuscles continues unabated in the central part. White blood-corpuscles migrate from the veins and the capillaries, but not from the arteries. Red blood-corpuscles also pass through the capillary walls by the passive process of diapedesis. Their number is not usually great, but, exceptionally, may be so considerable as to give a hemorrhagic character to the exudation. Coincidently with the processes of emigration and of diapedesis, the fluid constituents of the blood filter through the walls of the vessels. This fluid exudation resembles in its composition the plasma of the blood, but it contains less albumen. It contains the fibrin-generators, and, in most places, finds the conditions necessary for the spontaneous coagulation of the fibrin. A fibrinous effusion is, in the vast majority of cases, an inflammatory exudation. In simple inflammations of mucous membranes and in suppurative inflammations (abscesses), no fibrin is formed. By a process of reasoning which cannot be entered into here, Cohnheim con-

cludes that these various phenomena of inflammation can be explained only upon the assumption that the effect of the inflammatory irritant is to produce a molecular alteration in the walls of the vessels, which increases their permeability to the fluid and corpuscular elements of the blood, and increases the friction between the blood and the vessel-wall.

While the accuracy of Cohnheim's observations of the process of inflammation in frogs has been established, and their applicability to the same process in man has been recognized, there has been much controversy as to the part taken by the fixed cells outside of the vessels in the inflammatory process. Do they produce pus-cells, as Virchow taught? It is maintained by Cohnheim that the sole origin of pus-cells is to be found in emigration of the white blood-corpuscles, and that the fixed cells in inflammation either remain unchanged, or degenerate, or proliferate and produce other cells of their kind (regenerative process), but never give rise to pus-cells. On the other hand, Stricker and his school hold to the original doctrine of Virchow that all varieties of fixed cells—connective-tissue cells, epithelial cells, nerve-cells, muscle-cells—proliferate in inflammation and produce pus-cells. The difficulty in determining these points at issue lies chiefly in the fact that it has not yet been found possible to observe satisfactorily the process of change in the living fixed cells during inflammation, so that we are compelled to infer the nature of the process from a study of the phases, the interpretation of which is often various and open to fallacies. Especially is this true of the attempt to interpret the significance of phases apparently transitional between one form of cell and another, and to judge of the origin of a cell from its form. Hence, the evidence that fixed cells produce pus-cells is of a different nature and less convincing than the proof that pus-cells come from emigrated white blood-corpuscles. It is impossible to describe here the numerous experiments and observations made with reference to the settlement of this question. It must suffice to state that the weight of evidence is decidedly in favor of the view that fixed cells do not remain passive in inflamed parts, but that they become amœboid, proliferate, and produce young cells. Unless we arbitrarily restrict our definition of pus, these young cells are to be regarded as pus-cells, which may, therefore, be derived from either emigrated white blood-corpuscles or from fixed cells. The dominating elements in acute inflammation, however, are the emigration of white blood-corpuscles and the exudation of the fluid constituents of the blood in consequence of as yet undefined changes in the vascular walls.

As is evident from the foregoing description, the *products* of inflammation are fibrin, serum, pus-cells, and red blood-corpuscles. In inflammation of mucous membranes an increased secretion of mucus may take place. Exudations are classified as *fibrinous*, *serous*, *purulent*, *hemorrhagic*, and *mucous*, according to the relative proportion of the inflammatory products which they contain. *Fibrinous* exudation is best illustrated by the acute inflammations of serous membranes, where the fibrin is deposited as a layer upon the serous surfaces. These fibrinous layers can be readily stripped off, and are sometimes called *false membranes* and *coagulable lymph*. More or less white and red corpuscles are present in the meshes of the fibrin, and in the interior of the serous sac is a variable amount of fluid containing also fibrin and exuded cell-elements. Fibrinous exudation may be present also in inflammation of the solid tissues, in the air-cells of the lung, and upon mucous membranes. Fibrinous exudation upon mucous surfaces is called croupous or diphtheritic in accordance with a distinction to be explained hereafter. *Serous* exudations bear considerable resemblance to transudations, but they are generally richer in albumen and in cells. The main distinction, however, is that they appear with the signs of inflammation. The exudation in so-called collateral œdema (which is really inflammatory) is generally serous, likewise the exudation

in the early stage of many inflammations of mucous membranes. Inflammatory affections of the skin are accompanied often by the formation of vesicles containing serous exudation. Although pus-cells are present in all inflammatory exudations, it is only when they are sufficiently numerous to render it opaque that the exudation is said to be *purulent*. Pus consists of a fluid part (liquor puris) and of cells. Pus-cells are round, membraneless, and contain usually two or three nuclei inclosed in a cell-body of protoplasm, in which, as a rule, molecules of fat are present. Pus-cells belong to the widely distributed group of cells known variously as leucocytes, lymphoid cells, wandering cells, embryonic cells, small, round, indifferent cells. Their origin from emigrated white blood-corpuscles has been described. It is believed that pus-cells increase in number by division. Inflammations producing pus are suppurative. The pus may be exuded upon free surfaces; it may infiltrate the tissues (purulent infiltration); or it may be contained in cavities produced by the breaking down of tissue. Such cavities containing pus are called *abscesses*. Some recent writers hold that all extensive suppurative inflammations are due to the action of bacteria. When the exuded red blood-corpuscles are sufficiently abundant to give a red color to the exudation, the inflammation is said to be *hemorrhagic*. According to Cohnheim, hemorrhagic exudations are referable to an intense action of the inflammatory irritant upon the vascular walls. Tuberculous, cancerous, variolous, and scorbutic inflammations of serous membranes are apt to be hemorrhagic. The source of the hemorrhage may be from rupture of the vessels or from diapedesis.

As has already been mentioned, the terms *croupous* and *diphtheritic* are applied to fibrinous exudations upon mucous membranes. Unlike the inflammations of serous membranes, the ordinary inflammations of mucous membranes are not accompanied by a fibrinous exudation. The term *catarrhal* is sometimes applied to these simple inflammations of mucous membranes characterized by an exudation of serum, mucus, and some pus-cells. According to the careful investigations of Weigert,[1] fibrin is present in the inflammations of mucous membranes only when the epithelial covering is partly or wholly destroyed. The epithelium may be destroyed from various causes, among the most important of which is coagulation-necrosis. The necrosis may extend deeper than the epithelium into the subjacent tissues. When only the epithelium is destroyed, the fibrinous exudation lies upon the membrana propria of the mucous membrane, from which it can be readily stripped off without loss of substance. This form of exudation is called *croupous*. When the primary necrosis involves the tissue-cells as well as the epithelium, the fibrinous exudation extends from the surface into the tissue of the mucous membrane, and cannot be removed without loss of substance. This second form of exudation is denominated *diphtheritic*. When the fibrinous exudation adheres closely to the mucous membrane without really infiltrating it, it is called *pseudo-diphtheritic*. It is to be observed that croupous and diphtheritic exudations require destruction of the epithelium only in one place, and that they may extend thence over the surface of the surrounding intact epithelium. The fibrin in croupous and diphtheritic inflammations is derived partly from the blood, partly from metamorphosis of the epithelial and other cells, and, perhaps, partly from fibrinoid degeneration of the intercellular substance (Neumann). Further details concerning these varieties of inflammation will be found in Part II. of this work, in connection with croup and diphtheria.

The term *parenchymatous inflammation* was introduced by Virchow to indicate the origin of the inflammatory process in the parenchymatous cells

[1] Weigert, Virchow's Archiv, Bd. 70 and 71.

of an organ. These, for example the hepatic cells, under the influence of an irritant, swell up, become more granular than normal, proliferate, or, more frequently, undergo fatty degeneration and perhaps return to their healthy condition. The propriety of regarding these changes as inflammatory is at least doubtful. Most of them are also embraced under the names albuminous or parenchymatous degeneration. Many writers, however, still make use of the expression parenchymatous inflammation, especially with reference to the kidney, liver, and spinal cord.

The terminations of inflammation may be various. A complete restoration of an inflamed part to its normal condition is called *resolution*. This, as a rule, only occurs in the milder grades of inflammation. The fluid part of the exudation can be readily absorbed; emigrated white blood-corpuscles may re-enter the bloodvessels or may wander into the lymphatics, or they, as well as red blood-corpuscles and fibrin, may undergo fatty degeneration and then be absorbed. The formation of new connective tissue, or the *organization* of the exudation, as it is called, is a frequent termination of some forms of inflammation, particularly of the fibrinous exudation on serous membranes. Such organizing exudations are sometimes called *plastic* or *adhesive*. Fibrinous exudations in the bronchi are sometimes called plastic (plastic bronchitis) although no connective tissue is formed. It is certain that the fibrin is absorbed, taking no active part in the development of new tissue. The new connective-tissue cells may spring from emigrated white blood-corpuscles or from the pre-existing connective-tissue cells (including endothelial cells). The new tissue is at first very rich in capillaries, derived probably from the old capillaries, and in cells. Subsequently it becomes more fibrous, less vascular, and it contracts. Considerable accumulations of pus cannot be absorbed, but, when not evacuated, either remain without changing their consistency or become inspissated. Such dried masses of pus may undergo cheesy and calcareous transformations, and, becoming encapsulated, remain innocuous.

Chronic inflammations may be secondary to the acute, or subacute from their origin. In the latter case they may be unattended by any free exudation. Chronic inflammation most frequently results in the formation of new connective tissue.

CHAPTER III.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(CONTINUED.)

Pathological New Formations—Regeneration—Hypertrophy—Tumors—Carcinoma.

Active Alterations of the Tissues—Pathological New Formations.

THE active alterations of the tissues constitute the second division of the general pathological changes to be considered in this part of the work. These active alterations embrace the pathological new formations which will be grouped under the headings *regeneration*, *hypertrophy*, and *tumors*.

The pathological new formations are the result of increased activity of cells which are incited to abnormal growth and proliferation. It is to be borne in mind that the modern conception of a cell is based, not upon its etymological

significance, but upon the presence in it of living matter or protoplasm (also called bioplasm). Even formless clumps of protoplasm are sometimes called cells. Cells in the animal body are generally, if not always, provided with nuclei, and are usually devoid of enveloping membranes. Cells multiply by division. The multiplication of cells by endogenous growth and by budding has not been established. As the process is usually described, the first step in the proliferation of a cell is the division of its nucleus, and this is followed by division of its body or protoplasm, each segment surrounding one of the nuclei. Recent observations show that peculiar alterations in the nucleus, characterized by the appearance of a delicate reticulum, forming the so-called nuclear figures, usher in the process of segmentation. The doctrine of the so-called specialization of cells bears upon pathological new growths. Embryological researches have shown that after the formation of the three blastodermic layers, the cells in each produce only certain kinds of cells and tissues; that, for instance, connective tissue and muscle can spring only from the middle blastodermic layer, and epithelium only from the external and internal blastodermic layers (part of the genito-urinary epithelium possibly excepted). There is much which supports the view that under pathological conditions definite cells can be reproduced only by their kind, that, for example, new epithelial cells are always the offspring of pre-existing epithelium, and cannot be developed out of connective-tissue cells or white blood-corpuscles. This view is best established for epithelial and nervous tissue. Connective-tissue cells, however, can be produced apparently by emigrated white blood-corpuscles as well as by pre-existing connective-tissue cells.

Regeneration.

The subject of the regeneration of tissues after their destruction by wounds and pathological processes, is treated of *in extenso* in works on surgical pathology, and will be considered here only in outline. Some structures are reproduced with great ease, for example, connective tissue and epithelium; others with more difficulty, as muscular tissue and peripheral nerve-fibres, and, finally, others not at all, such as the central nervous system and the parenchyma of most organs.

Fibrillated connective tissue is present in nearly all pathological formations. It may be produced slowly out of the pre-existing connective tissue, or it may be formed out of germinal or granulation-tissue as it is called. This granulation-tissue is composed chiefly of round and spindle-shaped cells with scanty and ill-defined intercellular substance, and with bloodvessels without compact walls. The granulation-cells may be derived from emigrated white blood-corpuscles or from proliferated connective-tissue cells. The round cells become spindle-shaped, and finally assume the various forms characteristic of connective-tissue cells; the intercellular substance increases in amount, probably at the expense of the cells, and becomes distinctly fibrillated, and the round and fusiform cells, when they constitute the embryonic walls of the capillaries, change into flat endothelial cells. The fully formed fibrous tissue is not so rich as the granulation-tissue in cells and bloodvessels, some of which therefore are destroyed in the process of development. The newly formed bloodvessels may be, as described, channels simply hollowed out between the granulation-cells which then constitute their walls. The more usual method of their formation, however, seems to be by protoplasmatic offshoots from pre-existing capillaries. As described by Arnold, conical prolongations of protoplasm project from the capillary walls at certain points and unite with similar offshoots from other points. These prolongations are at first solid, but subsequently become hollowed out in their centre, the cavity thus formed communi-

cating with the lumen of the capillary vessels and receiving blood from them. At the same time nuclei develop, and the protoplasm divides around the nuclei into cells which now represent the endothelium of the newly formed capillaries. By additions to their coats of connective tissue and of smooth muscular fibres, and by widening of their lumina, these capillaries may change into arteries and veins. Among the circumstances under which connective tissue and bloodvessels are formed in the manner described, may be mentioned the repair of wounds, the healing of ulcers, and the development of adhesions after inflammation of serous membranes. The regenerative changes frequently proceed side by side with inflammatory alterations, from which they cannot usually be clearly separated.

Epithelium is endowed with an especially active power of regeneration. It has been experimentally demonstrated[1] that incised wounds of the cornea may be completely filled by newly developed epithelial cells within twenty-four hours. Nearly all recent observations go to prove that the new epithelium is always the offspring of the pre-existing epithelial cells.

Regeneration of *striated muscular fibres* occurs after their degeneration in fevers, particularly typhoid fever, and in some other diseases, and sometimes after their destruction by wounds, especially subcutaneous wounds. Defects in muscular tissue by wounds, however, are more frequently filled by cicatricial connective tissue. Whether the new muscular tissue is produced only from the old, or is produced from cells in the interstitial tissue (perimysium internum) has not been satisfactorily proven. Both views have their adherents.

The investigations concerning the regeneration of *peripheral nerve-fibres* have been many, but have not led to entire unanimity of opinion. Section of peripheral nerve-fibres is followed by their rapid degeneration from the point of section to their peripheral terminations. The degenerated peripheral nerve-fibres are replaced by new axis-cylinders which grow probably from the intact axis-cylinders in the central portion of the nerve. These axis-cylinders subsequently become invested with myeline and tubular sheaths. Notwithstanding some apparently confirmatory observations, there is no conclusive evidence that nerve-elements are regenerated in the central nervous system of the adult. This is certainly true as regards the reproduction of ganglion-cells.

The consideration of the reproduction of bone and of cartilage, belonging almost exclusively to surgery, cannot be entered into here.

Hypertrophy.

The term hypertrophy is applied to enlargement of a part from an increase of its normal constituents, the structure and arrangement remaining essentially unaltered. Parts which become enlarged in consequence of a deposit of materials foreign to their normal composition, or from a disproportionate excess of certain of their normal constituents, are not, properly speaking, hypertrophied. Two forms of hypertrophy have been distinguished, namely, *simple* or *true hypertrophy*, and *numerical hypertrophy* or *hyperplasia*. In simple hypertrophy there is an increase in the size of the anatomical elements, but not in their number; in hyperplasia the number of these elements is augmented. It is not usually practicable to carry out this distinction, as the two forms of hypertrophy are frequently combined. Hypertrophy may proceed from a diminution of the disintegration or waste naturally incident to the life and activity of cells, while the process of assimilation continues in normal force; but it more frequently results from an excess of appropriation, by the

[1] v. Wyss, Virchow's Archiv, Bd. 69, 1877.

part, of nutritive supplies. This excess of nutriment is generally consequent upon exaggerated and prolonged increase of the function of the part. The most frequent examples of hypertrophy are the physiological hypertrophy of the voluntary muscles following persistent exercise, and the pathological hypertrophy of the heart when it is called upon to overcome abnormal obstacles to the circulation, such as are presented by valvular lesions. Hypertrophy of the muscular tunic of the bladder in cases of long-continued urethral obstruction, also illustrates the production of this lesion by prolonged increase of function.

Hypertrophy of one of the kidneys usually ensues when the function of the other is either lost or greatly impaired. This is found to be the result of the removal of one of the kidneys in an inferior animal; under these circumstances the task of excreting the urine falls upon a single organ, its functional activity is doubled, and, as a result, the organ becomes enlarged. The examples of hypertrophy which have been cited, are conservative lesions and conduce to the welfare of the body. Microscopical examination in muscular and in glandular hypertrophies, reveals an increase in the number and usually in the size of the muscular fibres and of the epithelial cells. The increase in amount of the connective tissue of a part which is for a long time hyperæmic, especially when the hyperæmia is due to inflammation, may be referred partially to the augmented supply of nutriment, and thus is to be considered as hypertrophic.

Tumors.

Tumors constitute pre-eminently the pathological new growths. The boundaries of the conception attached to the term tumor cannot be easily defined. Tumor literally means swelling, but not every morbid swelling is a tumor in the technical sense. Particularly to be separated from real tumors are swellings due to inflammatory processes, to œdematous infiltration, and also, though less easily distinguished, those consequent upon hypertrophy. Tumors are composed of anatomical elements similar to those present normally in the body. The terms *homologous* and *heterologous* no longer indicate the presence or absence of elements wholly foreign to the normal organism; but morbid growths are now called homologous when their structure is similar to that of the parts in which they are developed, for example, a fatty tumor in adipose tissue; while the term heterologous is applied to growths differing in structure from the parts in which they are seated, for instance, epithelial tumors in connective tissue.

Tumors are classified and named according to the physiological type of tissue of which they are composed. This basis of classification proposed by Johannes Müller has been firmly established by the exhaustive researches of Virchow. We thus distinguish tumors formed after the type of connective tissue in its manifold forms, of epithelium, of muscular tissue, of nervous tissue and of bloodvessels. Mixed tumors are those in which two or more forms of tumor are combined. Cysts occupy a special place among the tumors. Many are to be ranked rather among the passive than the active alterations of the tissues. Three forms of cysts may be distinguished: *first*, those due to dilatation of pre-existing cavities by liquid accumulations (such are the retention cysts); *second*, those resulting from the formation of a pathological cavity by the softening and breaking down of tissue; and *third*, those actually of new formation, as the dermoid cysts.

An important clinical division of tumors is into *benign* and *malignant*. The signs of malignancy are the invasion of the surrounding tissues, the property of local recurrence, the formation of metastases, and the development of a cachexia. Benign tumors displace, compress, and perhaps lead to atrophy

of the tissues in their neighborhood, whereas, those tumors which grow into and invade the surrounding tissues are generally malignant. Tumors which return *in loco* after their removal, are frequently, although not necessarily, malignant. Another evidence of malignancy is the development, in various parts of the body, of secondary or metastatic tumors of the same structure as the primary growth. The metastases are believed to be due to the transportation by the blood or lymph-current of cells from a primary or secondary tumor. The cachexia is now generally believed to be the sequel of the tumor, and not a primary dyscrasia. With one exception, it has not been found possible to determine anatomical criteria of malignancy in a tumor. The exception is carcinoma which is always malignant. From this statement it is not to be inferred that recovery may not take place after complete removal of the tumor. Some forms of sarcoma may prove equally malignant, but malignancy is not a necessary attribute of sarcoma, as it is of carcinoma. Of other tumors, a considerable number prove, under exceptional circumstances, malignant.

We possess very little positive information as to the causation of tumors. The question has been much discussed as to the local, or the dyscrasic, origin of tumors, particularly of malignant tumors, but it now seems to be settled in favor of their local origin. Transmission by inheritance has been shown to be an important predisposing influence in the development of some tumors, particularly carcinoma. Local irritation, such as results from injuries, has been often adduced as a cause of the growth of tumors; but this influence of pathological and of physiological irritation has been doubtless exaggerated, and, at the most, can be regarded only as an exciting cause. Cohnheim[1] has recently advanced the hypothesis that all true tumors (he separates from these a group denominated infectious tumors, to be mentioned presently) are the result of some abnormality in embryonic development. According to this theory, the germs of the tumor, perhaps consisting of misplaced embryonic cells, are brought by the individual into the world. They may remain dormant for a variable length of time, and then, under the influence of some exciting cause, possibly an injury, may begin to grow. The limits of this work will not permit a consideration of the ingenious arguments by which this hypothesis is supported.

There is a class of tumors, for which the name *infectious* has been proposed, which are closely allied to inflammatory new formations, and, in fact, are classified among them by some writers. They are formed after the type of lymphatic or of granulation tissue. The most important of this group of tumors are tubercle and gumma. On account of its importance in medical pathology, tubercle will receive especial consideration under a separate heading. Of the other tumors, space will permit hardly more than a mere enumeration. Carcinoma, however, will be considered somewhat more in detail, on account of its frequency and importance.

Tumors in structure analogous to some of the different forms of connective tissue:—

1. After the type of embryonic tissue—*sarcoma.* Of all varieties of tumor, sarcoma and carcinoma are undoubtedly the most important. Sarcomata are composed almost wholly of cells, and are classified according to the form of cell which predominates. An important general division is into small-celled and large-celled sarcomata, of which the former are usually the most malignant. The three leading varieties of sarcoma are, *first*, round-celled, *second*, spindle-celled, and, *third*, giant-celled or myeloid sarcoma. The cells are separated from each other by a small amount of intercellular substance

[1] Cohnheim, Allgemeine Pathologie, Bd. I. p. 631 et seq.

or stroma, which may be formless or fibrillated. Some modern writers recognize an alveolar sarcoma, but in most of the so-called alveolar sarcomata the cells in the apparent alveoli are not in immediate contact, as in carcinoma, but are separated by a scanty amount of intercellular substance. Where this is not the case, the propriety of calling the tumor sarcoma, and not carcinoma, is questionable. Sarcoma is very often combined with other forms of tumor, as in osteo-sarcoma, myxo-sarcoma, glio-sarcoma, etc. Melano-sarcoma is characterized by the presence of black pigment-granules in the cells. Its most frequent point of departure is the choroid of the eye and the integument. As sarcoma springs from the universally distributed connective tissue, there is hardly any part of the body from which it may not take its origin. The giant-celled and the ossifying sarcomata generally spring from bone or periosteum. It has already been mentioned that sarcoma embraces both benign and malignant growths. The smaller the size and the larger the number of the cells of the tumor, the more malignant and rapidly growing is it, as a rule. Hence the round-celled sarcomata and the melano-sarcomata are the varieties most to be feared.

2. After the type of mucoid tissue—*myxoma.* Myxomata present more or less of a translucent, gelatinous appearance. They spring from connective tissue. They have been observed as multiple tumors growing from the interstitial tissue of the nerves (constituting a variety of false neuromata), but they are generally local. They are benign, as a rule. Metastases have been observed.

3. After the type of lymphatic tissue—*lymphoma, lymph-adenoma, lympho-sarcoma.* Multiple tumors of this variety appear in the lymphatic glands, spleen, and elsewhere in leucocythæmia and pseudo-leucocythæmia. Little accumulations of lymphoid cells, also called lymphomata, sometimes appear in the liver and elsewhere in typhoid fever and other infectious diseases. Tumors composed of tissue resembling granulation-tissue are called by Virchow *granulomata.* He includes tubercle and *gumma* under this head. It is not, as a rule, practicable to distinguish between granuloma and lymphoma as generic names of distinct classes of tumors. Tubercle will be subsequently considered. Gumma is also called syphiloma. Gumma is a late, but extremely characteristic lesion of syphilis. A gumma consists of a nodule, usually larger than a tubercle, composed, at first, almost wholly of lymphoid cells. Later the centre of the nodule undergoes a peculiar hard caseous metamorphosis, while the periphery consists of round and fusiform cells. Blood-vessels can be recognized sometimes even in the cheesy centre. Gummata may grow in the liver, membranes of the brain, heart, testicle, bone, and other parts. They often in part disappear spontaneously or under appropriate treatment. They belong, with tubercle and many lymphomata, to the group of infectious tumors which are believed to be the result of local or constitutional infection.

4. After the type of neuroglia—*glioma.* The gliomata are confined to the brain, spinal cord and retina. The most typical gliomata are composed of peculiar branched cells called spider-cells and brush-cells, similar to those present in the normal neuroglia or connective tissue of the central nervous system. They are often combined with sarcomatous tissue (glio-sarcomata). They frequently appear in the brain more as infiltrations than as tumors. They do not occasion metastases, but are often the cause of death from their localization in important parts.

5. After the type of fibrillated connective tissue—*fibroma.*

6. After the type of adipose tissue—*lipoma.*

7. After the type of cartilage—*enchondroma.*

8. After the type of bone—*osteoma.*

9. After the type of bloodvessels—*angioma.*

The last five varieties of tumor have, clinically, as a rule, a purely local importance. Enchondroma may exceptionally become generalized, and the same is true, in a less degree, of the other forms, except angioma which never gives rise to metastases.

Tumors composed of muscular tissue—myomata:—

1. After the type of striated muscle—*rhabdomyoma* or *myoma striocellulare.* Tumors composed of striated muscle-cells are very rare, and are generally congenital. They have been found in the kidneys, testicle, and other parts.

2. After the type of smooth muscle—*leiomyoma* or *myoma lævicellulare.* The most frequent seat is the uterus, where, combined with more or less fibrous tissue, the myomata constitute the so-called uterine fibroids.

Tumors composed of nervous tissue—neuromata:—

It is customary to call all tumors growing from the nerve-trunks neuromata. It is therefore necessary to distinguish between *true* and *false* neuromata. Tumors composed actually of newly formed nerve-fibres occur, but they are rare, the majority of the so-called neuromata being myxomata and fibromata. According to Klebs, glioma develops from nerve-elements.

Tumors the most important constituent of which is epithelium—papilloma, adenoma, carcinoma including *epithelioma:—*

A papilloma is composed of papillæ, often very large and irregular in shape, which consist, like normal papillæ, of vascularized connective tissue covered with epithelium of variable thickness. This tumor is due sometimes apparently to hypertrophy of the papillæ in consequence of chronic inflammation. The soft papillomata of the bladder, rectum, and uterus constitute the most important forms, and often occasion considerable hemorrhage.

An adenoma is composed of glandular tissue, in which the type of the gland can be easily recognized. It always develops from a pre-existing gland. The acini, tubules, or follicles of an adenoma are not completely filled, as a rule, with the epithelial elements but preserve a lumen. This fact, together with the distinctly preserved glandular type, distinguishes adenoma from carcinoma. As important examples of this variety of tumor may be cited, adenoma of the breast, of the uterus, of the rectum, and of the ovary. The large multilocular ovarian cysts are to be ranked among the adenomata. Although allied to carcinoma in development and structure, adenoma is a benign growth.

Carcinoma.

Most modern pathologists agree in making the criterion of carcinoma or cancer (the two terms are interchangeable) a definite anatomical structure, and no longer call a tumor cancer simply because it possesses the signs of malignancy, which have been enumerated. Other tumors, as well as cancer, may assume a malignant course. The essential feature of carcinoma is, not the presence of any particular form of cell, for *specific* cancer-cells do not exist, but the arrangement of the cells in spaces called *alveoli* which lie imbedded in vascular connective tissue called *stroma.* The name alveolus, as here applied, is somewhat misleading, as the spaces may be of any shape or size, and always communicate with each other. Thus, upon section, the cancerous alveoli appear broad or narrow, round or elongated or branching, and contain from three or four to several hundred cells. The cells within these alveoli are sometimes called the cancer-cells in distinction from the cells in the intervening stroma. These cancer-cells may be of the most variable size and

shape; they are at least larger than white blood-corpuscles, and, in a general way, may be said to resemble epithelial cells in shape. This resemblance is sometimes close, at other times remote. In their relation to each other, however, the resemblance to epithelium is exact. The cancer-cells in an alveolus lie in close proximity to each other, not separated by any intercellular substance, or, at least, by no more than a scanty cement-substance like that between epithelial cells. If the cells be brushed or shaken out of an alveolus, this space is found to be empty. All of the tissue between the alveoli forms the stroma which consists of fibrillated connective tissue usually very vascular and at times very rich in cells. An old and still employed classification of cancers is into *scirrhus*, *encephaloid* or *medullary*, and *colloid* cancer. This subdivision, not being based upon essential anatomical differences, is not very satisfactory. The terms scirrhus and encephaloid refer to the consistency of the tumor. A scirrhus is a hard cancer in which the fibrous stroma predominates; encephaloid or medullary cancer is soft in consequence of the small amount of stroma and excess of cancer-cells. There is no essential structural difference between the two forms. The encephaloid cancer is naturally the most rapid in its growth, and the most malignant. Its cells are usually smaller than in other forms of cancer. In colloid cancer the alveoli contain partly cells and partly a translucent, gelatinous material which is thought to be derived, by colloid metamorphosis, from the cancer-cells. The alveolar structure of colloid cancer being generally evident to the naked eye, this variety has received also the name *alveolar cancer*, although, strictly speaking, every cancer is alveolar. The nature of colloid cancer, and even the propriety of classifying it with other forms of cancer, have not been established. It grows most frequently from the abdominal viscera or peritoneum, and is less malignant than other species of cancer.

A subject which has been discussed of late years, perhaps, more than any other pertaining to the pathology of carcinoma, relates to the origin of cancer-cells. It has been the teaching of Virchow, in accord with his scheme of pathogenesis, that cancer-cells develop out of connective-tissue cells. On the other hand, the belief has been gaining ground, chiefly through the researches of Thiersch and of Waldeyer, that cancer-cells not only resemble epithelial cells in shape and in relation to each other, but that they are actually the offspring of epithelial cells. It is Waldeyer's view that all varieties of cancer are of epithelial origin, and are, therefore, strictly speaking, epitheliomata. The epithelial origin of the flat-celled skin cancers, and of the cylindrical-celled cancers of certain mucous membranes, has been established without doubt. The term epithelioma or epithelial cancer is, therefore, frequently restricted to these two forms. But the epithelial derivation of the great majority of the other forms of cancer in which the cells less perfectly preserve the type of epithelium, has been rendered extremely probable. Nevertheless, there are exceptionally tumors which in structure must be ranked as cancers, but in which the cells not only have not been proven to spring from epithelium, but are almost certainly derived from connective-tissue cells (including endothelium). As our means of determining the genesis of cells are so imperfect, it seems best for the present not to introduce the epithelial origin of the cells as an element in our definition of cancer, but to rely solely upon the alveolar structure above described, and to do this notwithstanding the belief that the great majority of cancers are of epithelial origin. It is an interesting fact that, as a rule, cancer-cells conform to the type of epithelium of the part in which they primarily grow. Thus in cancers of the skin, lips, penis, vagina, the alveoli are filled with cells resembling flat epithelium. In fact, some of these cells usually undergo the metamorphosis into keratine, as do those on the skin, and these horny cells become compacted together into little balls called *cancroid*

pearls, which lie among the cells of the alveoli, and are extremely characteristic of this form of cancer. These skin-cancers are also called epitheliomata and cancroids, and, although malignant, are less likely to produce metastases than most other forms of cancer. Cancer of the stomach is often distinctly cylindrical-celled in correspondence with the type of epithelium normally present there. A more or less distinct glandular arrangement of the alveoli can be made out usually in these and in many other forms of cancer. The term simple cancer, carcinoma simplex, is sometimes used to designate those ordinary cancers in which the cells are not distinctly flat or cylindrical, in distinction from the epitheliomata in the restricted sense. In their growth the cancer-cells push their way especially into lymph-vessels and lymph-spaces, so that oftentimes the alveoli are dilated lymph-spaces. The metastatic or secondary growths which are such a frequent accompaniment of cancer, preserve, with very few exceptions, the type of the primary growth. The material, doubtless consisting of cells from the primary tumor which produces the metastases, is transported especially by the lymphatic vessels, so that the neighboring lymphatic glands are early involved. The metastases may also occur through the bloodvessels, as is the rule with sarcoma. Carcinoma is purely local in its origin, and is not preceded by any dyscrasia. The cancerous cachexia follows the development of the primary and secondary growths. As cancer most frequently develops after forty years of age, the time of life becomes an important factor in the differential diagnosis. Nevertheless, cancer may occur early in life. In fact, cancer of the kidney is more frequent in children than in old people. On account of the frequency of cancer of the breast and of the uterus, females are more subject to cancer than males. Carcinoma may grow from any organ possessing epithelium. Primary cancers of bone, lymphatic glands, serous membranes, and other parts devoid of epithelium are certainly very rare. A frequent metamorphosis in cancers is fatty degeneration with disintegration of the cell-elements. In this way ulcerations are produced. By combined fatty degeneration and increase of the fibrous stroma, a cancerous tumor may be much reduced in size and activity, but it is doubtful whether recovery ever takes place in this way.

CHAPTER IV.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(CONTINUED.)

Tubercle—Scrofula—Passive Alterations of the Tissues—Atrophy—Necrosis.

Tubercle.

THE morbid products embraced under the name *tubercle* are of great importance, in view of the frequency of the affections in which they occur, and of the extent to which these contribute to mortality. Notwithstanding the vast amount of research devoted to the subject, we are still ignorant as to various points relating to the nature, structure, and pathological position of tubercle. The term tubercle, signifying, originally, any small nodule, was applied, first by Baillie and by Bayle, to small, gray, semitransparent granu-

lations which appear in the lungs, and sometimes in other organs of the body, in pulmonary phthisis. But more constant and striking than the presence of these minute gray granulations, is the appearance in phthisical lungs of larger or smaller masses of a dry, yellowish, cheesy-looking material. These cheesy masses were called yellow or crude tubercles, and were at first held to be distinct from the gray tubercle. Laennec, whose teachings concerning pulmonary phthisis have been of great influence, maintained that the gray tubercles precede and give rise to the crude or yellow tubercle by, either separately or after coalescence with each other, undergoing the cheesy metamorphosis. He gave the name *infiltrated tubercle*, in distinction from the tuberculous granulation, to the diffuse caseous deposits. He emphasized cheesy degeneration as the essential characteristic of tubercle. For him every caseous mass was a tubercle, and pulmonary phthisis in every form was one disease, namely tuberculosis.

These views of Laennec have been opposed by Virchow and other observers since about the middle of the present century. Virchow proved that many pathological products, other than tubercle, can undergo the same caseous metamorphosis, as, for instance, pus, cancer, the products of pneumonia, etc., and that, therefore, there is nothing specifically tuberculous in the presence of cheesy material. The only real tubercle, according to Virchow's doctrine, is the gray, miliary granulation with its metamorphoses, and no process is to be called tuberculous unless these granules are present. He showed that much of the deposit called by Laennec crude and infiltrated tubercle, consists in reality of caseous inflammatory products. Great confusion has arisen from the attempt to separate the caseous inflammatory from the caseous tuberculous products. Inasmuch as the caseous material itself furnishes little clue as to its origin, and inasmuch as the tuberculous and the purely inflammatory processes are in progress usually side by side, it becomes extremely difficult to define each, and to assign to it its relative importance. Hence it is that some writers, especially those who have followed the teachings of Niemeyer, hold phthisis to be essentially a broncho-pneumonia, in which tuberculosis, at the most, plays an insignificant part. During the last few years, however, there has been a reaction in favor of the doctrine that the most constant and characteristic changes in pulmonary phthisis are tuberculous.

One of the chief obstacles met with in the endeavor to obtain a clear conception of the nature and extent of the tuberculous process, is the lack of agreement among pathologists as to the histological criteria of tubercle. According to Virchow, the gray, miliary tubercle is a non-vascular nodule, smaller than a millet-seed, composed of lymphoid cells with an inherent tendency to undergo a cheesy, or, more rarely, a fibroid metamorphosis. The investigations of Wagner, Langhans and Schüppel have demonstrated for many tubercles a more complicated structure, namely, a framework of adenoid or reticular connective tissue, inclosing in its meshes lymphoid cells, larger endothelioid cells, and one or more multinuclear cells called giant-cells. While this giant-celled or lymphadenoid tubercle may be considered the most complete and characteristic tubercle, the attempt to refuse the name tubercle to granulations not presenting this structure has not been successful. It is true that the giant-cells and especially the endothelioid cells are present in most tubercles, but they may be absent, as is usually the case in tubercles of the pia mater. The nodular accumulation of lymphoid cells, with or without endothelioid cells and giant-cells, the non-vascularity, the inherent tendency to become cheesy, the multiple appearance, are the anatomical criteria of the tuberculous granule. It has been proposed to call tubercles of the simplest structure, namely, those consisting merely of a nodular accumulation of lymphoid cells, *embryonic tubercles*, on the assumption that endothelial and giant-cells

are derived from the lymphoid cells. The caseous metamorphosis, upon which Laennec justly laid so much stress, is a regressive change which has been sometimes referred to the imperfect nutrition of the cells in consequence of the absence of vessels in the nodules. It has also been attributed to an inherent, not otherwise definable, tendency in the cells of the tubercle. They who admit the existence of a specific tuberculous virus ascribe the cheesy degeneration to its influence. This caseous metamorphosis is not a mere dry, fatty degeneration, but it is due to the process of coagulation-necrosis. The cells lose their nuclei, of which only minute, if any, fragments remain. The dry amorphous detritus which remains, consists of albuminous and some fatty granules. The cheesy material may further break down and soften, and its place be occupied by cavities. A rare metamorphosis of tubercle is into fibrous tissue—fibroid tubercle. Tubercles in the lungs are most frequently developed in the walls of the small bronchi, but they are also to be found in the sheaths of the vessels and in the interstitial tissue.

It is not the place here to enter into the pathology of pulmonary phthisis except in so far as it may contribute to a clearer conception of tubercle. In the vast majority of all cases of phthisis, well-defined tuberculous granulations are present in the lungs in combination with diffuse inflammatory changes. There are, moreover, frequently present certain nodules and infiltrations, the anatomical structure of which has been established, which some writers regard as tubercles, and others do not. For example, it is very common to find, especially in cases of rapid phthisis, nodules, of which the centre is a small bronchus, filled with pus, and the wall densely infiltrated with lymphoid cells. The periphery of the nodules is composed of air-cells, the walls and cavities of which contain lymphoid and endothelioid cells. Cheesy degeneration takes place in the centre, and extends peripherally. Giant-cells may make their appearance, but not necessarily. According to some, such a nodule is to be assigned to bronchitis, peribronchitis, and catarrhal penumonia combined. Recent French writers call it a *pneumonic tubercle.* Tubercles may be present in any organs or tissues of the body except those which are non-vascular. In acute miliary tuberculosis, they are scattered over the greater part of the body. In chronic pulmonary phthisis, they are generally confined to the lungs, pleura, bronchial glands, larynx, and intestines, but they may be present in other parts.

We possess no definite information as to the origin of the cells in the tuberculous granulations, whether they are derived from emigrated white blood-corpuscles, from endothelial cells, or from connective-tissue cells. Ziegler has shown that cells resembling the endothelioid and the giant-cells of tubercle may be formed by coalescence of white blood-corpuscles. Authorities disagree as to the rank to be assigned to tubercle among pathological products. It is classed by Virchow among the tumors. Some consider it to be of inflammatory origin, and, certainly, whether itself inflammatory or not, it is most intimately connected with inflammatory changes in surrounding parts.

Another interesting aspect of the subject relates to the question whether the tuberculous processes are due to infection with a specific poison, or not. An important discovery bearing upon this question was communicated to the French Academy of Medicine by Villemin in 1865. By inoculating rabbits and guinea-pigs with tuberculous material, he succeeded in producing a general tuberculosis, in all essential points analogous to the general miliary tuberculosis in man. Villemin contended for the existence of a specific poison, a tuberculous virus, as the cause of tuberculosis both in man and in animals. Since Villemin's publications, several experimenters have reported equal success by inserting under the skin material not tuberculous, as for instance bits of cork, paper, hair, etc. Klebs, however, who used certain precautions, failed to pro-

duce tuberculosis with all except tuberculous or cheesy material. The same is true of the later experiments of Cohnheim. Neither he nor Fränkel, in repeating their experiments with the necessary precautions, has been able to obtain the results which they published in 1868, in opposition to the non-specific nature of experimental tuberculosis. From an opponent, Cohnheim has, therefore, changed to a strong advocate[1] of the doctrine of a specific tuberculous poison. He finds that the virus is contained not only in the tuberculous granulation but in all of the cheesy products which appear in tuberculosis,—for instance, in the products of caseous pneumonia and in scrofulous lymphatic glands. From this stand-point, therefore, the caseous inflammatory processes in phthisis are just as specifically tuberculous as is the miliary granulation. Further experiments and observations are needed before the doctrine of the specifically infectious nature of tuberculosis can be accepted. There is sufficient evidence that tuberculosis may be produced by using the milk of tuberculous cows, to justify the employment of careful preventive measures.

Scrofula.

The term scrofula is of very old date, and is used with a rather comprehensive and indefinite latitude of signification. It is applied to a diathesis or constitutional condition observed especially in young persons who are the offspring of tuberculous parents or who are in bad hygienic surroundings. Scrofulous persons are prone to inflammations, particularly of the mucous membranes, lymphatic glands, skin, and periosteum. These inflammations are of a chronic character; the exudations have a tendency to cheesy degeneration, rather than to resolution or organization. The inflammatory products are rich in cells, many of which are larger than are usually present in inflammation. The lymphatic glands, especially those of the neck, enlarge, often coalesce with each other, and undergo cheesy metamorphosis. The name scrofula was adopted with reference to these glandular swellings in the neck. The various affections attributed to scrofula often disappear as the individual grows older and the hygienic surroundings are improved. There is an intimate relation between scrofula and tuberculosis. The cheesy deposits in scrofulous lymphatic glands are generally tuberculous. Many writers do not recognize the existence of scrofula as a special cachexia independent of tuberculosis.

Passive Alterations of the Tissues.

The passive alterations of the tissues will be considered under the heads *atrophy*, *necrosis*, *degenerations* and *infiltrations*.

Atrophy.

The term *atrophy* expresses a condition the reverse of hypertrophy. In atrophy the histological elements of a part diminish in size or in number, without undergoing further change of structure. Diminution of volume and of weight characterizes atrophy, unless a deposit of fat or of some other substance compensates for the loss of material. An atrophic organ is generally dry, firm, and anæmic. Atrophy may be a *physiological* process, as is the

[1] Cohnheim, Die Tuberkulose vom Standpunkte der Infectionslehre. Leipzig, 1880. The experiments of Cohnheim and Salomonsen were made by the inoculation of tuberculous material into the anterior chamber of the rabbit's eye. In three to four weeks after the inoculation an eruption of miliary tubercles appeared in the iris. These increased in size and became cheesy. Panophthalmitis followed. General miliary tuberculosis developed in three or four months. Tubercles were formed only after the inoculation of tuberculous material.

case with the normal involution of the thymus-gland and of the female genital organs. Senile atrophy is perhaps also to be included among the physiological atrophies, although pathological causes are often present. *An insufficient supply of nutriment* is a most efficient cause of atrophy both local and general. Examples of local atrophy due to this cause are the wasting of the hepatic parenchyma in cirrhosis of the liver and the atrophy of parts subjected to pressure (compression-atrophy). A general atrophy, although in unequal degree, of the organs and tissues of the body, is the result of insufficient supply of food and of mal-assimilation. *Functional inactivity* is another cause of atrophy. This atrophy may be in part explained by the diminished blood-supply which is known to attend suspended function. As examples of this functional atrophy may be cited the wasting of the muscles in paralysis, of the bone in anchylosis, of the intestine below a preternatural anus. *The withdrawal of nervous influence* may be a cause of atrophy. A rapid atrophy of the voluntary muscles follows degeneration and atrophy of the multipolar ganglion-cells in the anterior horns of the spinal cord, or lesions suspending the functions of the peripheral nerves which connect the muscles with these ganglion-cells. So rapidly does this atrophy progress, that it cannot be attributed merely to loss of function. It seems necessary to assign a trophic or nutritive function to these ganglion-cells. Examples of this *neuro-trophic atrophy* are progressive muscular atrophy, infantile spinal paralysis, and peripheral palsies.

The microscopical examination of atrophied parts reveals a diminution in number or in size of the cells, usually both. A division into *simple atrophy*, in which there is only a diminution in size, and *numerical atrophy* or *aplasia*, in which there is diminution in number of cells, is not of practical importance. In the atrophy of adipose-tissue cells, Flemming observed an infiltration of the cells with serum and an increase in the number of nuclei. This so-called *atrophic proliferation* shows that increase in nuclei is not sufficient evidence of an active proliferation-process. In the neuro-trophic muscular atrophies there is also an increase in number of the muscle-corpuscles and an increase of the interstitial tissue. In atrophy of the heart, a deposit of brownish pigment usually occurs in the atrophic muscular fibres, hence the name *brown atrophy*. In atrophy of the kidney and sometimes in muscular atrophy, especially in pseudo-hypertrophic paralysis, an excessive deposit of fat occurs about the kidney and between the muscle-fibres.

Necrosis.

The death of any part of the body is called *necrosis*.[1] The causes of necrosis are, *first*, arrest of the circulation, and, *second*, agencies which destroy the vitality of the cells. The causes which arrest the circulation may act primarily on the arteries, veins, or capillaries. Obstructions in the arteries lead to necrosis in situations where no sufficient collateral circulation can be established, as in the kidneys, spleen, and some parts of the brain (see embolism and thrombosis). Arterial obstruction in other parts, for instance in the extremities, also may occasion local death when the arteries are extensively diseased or the circulation feeble. The most important element in the production of *senile gangrene*, which affects by preference the lower extremities, is extensive atheroma of the arteries. Venous obstruction rarely leads to necrosis, on account of the relief usually afforded by numerous collateral channels. If all the veins of a part be occluded, so that no return circulation can

[1] Surgeons often confine the use of the term necrosis to death of bone.

exist, necrosis follows, as in strangulated hernia and in the constriction of a part by a tight bandage, where also arterial is combined with venous obstruction. Obstructions in the capillaries are generally due to agencies which also impair the life of the tissue-cells, as for instance the compression exercised by exudations, tumors, etc. Most of the agencies which cause disintegration of the cells act also upon the circulation. This second group of causes includes mechanical violence, certain chemical substances, extreme heat and cold, and the action of certain low organisms, particularly bacteria. Chemical substances act either by withdrawing water from the tissues or by entering into chemical combinations with the histological elements. The influence of certain bacteria in producing local death, is illustrated by the necrotic condition of the cells often observed around colonies of bacteria in malignant pustule, diphtheria, and pyæmia. Whether the bacteria produce these effects by means of a ferment, or by withdrawing nourishment from the tissue-cells, is uncertain. The gangrene of the extremities which follows the prolonged ingestion of ergot is usually attributed to the contraction of the small arteries induced by this substance. The endemic occurrence of ergotism from eating diseased grain seems to have disappeared. The parts of the body differ normally in their power of resistance to agents causing necrosis. Under pathological conditions, this resistant power may be so diminished that comparatively slight causes occasion necrosis. Thus, in feeble, bed-ridden persons, moderate pressure and uncleanness may suffice to produce necrosis in the form of bed-sores. These bed-sores (or decubitus, as they are called by German authors) may occur in a very short time, even in twenty-four hours after injuries and diseases involving the gray matter of the spinal cord. This acute necrosis is attributed to neuro-trophic disturbance. Diabetes mellitus is a disease in which the resistant power of the tissues is weakened, and in which gangrene sometimes occurs.

As there are many causes, so there are manifold forms in which necrosis appears. In the first place, a necrosed part may preserve nearly its normal appearance. This is true only of certain hard resistant substances, such as bone, cartilage, and tendon. An important distinction is that between *simple necrosis* and *necrosis with decomposition*. The latter is usually called *gangrene*, although this term is also often applied to forms of simple necrosis. One form of simple necrosis of the exposed parts of the body is called *dry gangrene*. In this the dead tissues dry up, shrink, and assume a dark color. Evaporation is greatly favored by loss of the epidermis. If the necrosis be accompanied by putrefaction, we have *moist gangrene*. In this, the affected part is humid, of a dark color from diffusion of blood-pigment, and of a penetrating odor. Bubbles of gas composed of ammonia, sulphuretted hydrogen, and other substances are generated in the tissues. Various crystals, as of leucin, tyrosin, blood-pigment, fatty acids, triple phosphates, are found. The decomposition is due to the action of a ferment generated by certain bacteria. Necrosis with decomposition is therefore usually met with only in parts of the body exposed to the air, as the extremities, the lungs, the uterus. If decomposition accompany necrosis in other parts of the body, for instance, the brain, it is in consequence of the transportation thither of some putrescent material, such as that carried by emboli from ichorous thrombi. A necrosed mass of tissue is called a *sphacelus* or *slough*. Necrosis of internal organs not exposed to the air may be in the form of simple softening without any attendant decomposition. A good example of this form of simple necrosis is the ordinary embolic softening of the brain.

One of the most important and interesting of the forms of necrosis is that to which Cohnheim has given the name *coagulation-necrosis*, and which has

been studied most carefully by Weigert.[1] Coagulation-necrosis consists in the transformation of protoplasm into a non-nucleated, coagulated, albuminous material resembling, if not identical with, fibrin. This coagulation may occur in all kinds of tissue, the cells of which possess coagulable protoplasm, and it may be an element in a variety of pathological processes. The nature of the process is believed by Weigert to be similar to that of the formation of fibrin from the blood. The presence of a so-called fibrin-ferment is essential for the coagulation of fibrin. In addition, according to Schmidt, both the fibrinogenous and the fibrinoplastic substances must be present, whereas Hammarsten holds that the fibrinogenous substance suffices. The ferment is furnished by the destruction of white blood-corpuscles, and, according to Weigert, may be produced also by the death of other cells. An essential condition, therefore, for this transformation of cell-substance, called coagulation-necrosis, is the death of cells under circumstances and in places in which they can be permeated by fluid containing the fibrinogenous substance. This condition is best fulfilled when cells die in the living tissues through which is constantly passing the lymph or serous transudation from the blood. There are certain influences which prevent coagulation when the conditions otherwise are present. Of these unfavorable influences may be mentioned suppuration, the agency of the bacteria of decomposition, and the preservation of the epithelium of mucous membranes (see Croupous and Diphtheritic Inflammations). The white infarctions which follow embolism of branches of the renal or splenic arteries, afford an excellent example of coagulation-necrosis. As already explained, the death of the tissues in these infarctions is due to ischæmia. To the naked eye these infarctions are light in color; they are firm, and frequently present in their periphery a hemorrhagic zone which does not extend into the interior in consequence of the resistance offered by the firmly coagulated mass to the entrance of blood. Microscopical examination shows that the cells in the anæmic district have lost their nuclei. At first the cell-contours are preserved, but subsequently the cellular outlines are destroyed. It is the loss of nuclei which constitutes the most striking microscopical change, the chemical alteration in the protoplasm being less evident. Leucocytes with intact nuclei wander in from the periphery. This anæmic necrosis is also present, but to a less extent, in pulmonary infarctions. In the anæmic softening of the brain there is no coagulation, in consequence of the absence of a sufficient amount of coagulable protoplasm. The so-called caseous metamorphosis in tuberculous and scrofulous products belongs to the domain of coagulation-necrosis. Coagulation-necrosis may attack individual cells as well as masses of tissue. In this respect the parenchymatous cells of an organ are less resistant than connective-tissue cells. Thus, coagulation-necrosis of the renal epithelium, without apparent change in the other tissue-elements, may be produced experimentally in animals by temporary ligation of the renal artery, or by subcutaneous injection of the salts of chromic acid. In croupous and in diphtheritic inflammations there is coagulation-necrosis of the epithelium of the affected mucous membrane, in the latter process combined with necrosis of the subjacent tissues. The formation of the smallpox vesicle is preceded by coagulation-necrosis of the lowest cells of the rete Malpighi. The so-called waxy degeneration of the muscles, such as occurs in typhoid fever, is apparently a coagulation-necrosis. Coagulation-necrosis of the white blood-corpuscles, resulting in their disintegration, occurs in white thrombi, and in fibrinous exudations upon serous membranes. Finally, this form of necrosis is the effect of certain forms of bacteria, as may

[1] Weigert, Ueber die pathologischen Gerinnungsvorgänge, Virchow's Archiv, Bd. 79, 1880.

be seen in the early stage of certain abscesses of the liver. The microscopical appearances and the chemical processes are not the same in all of the different forms of coagulation-necrosis which have been mentioned, but it is impossible to enter here further into histological and chemical details, some of which will be referred to in appropriate places in the second part of this work. Coagulation-necrosis and fatty degeneration may be associated.

CHAPTER V.

ANATOMICAL CHANGES IN THE SOLID PARTS OF THE BODY—(Concluded.)

Infiltrations and degenerations—Parenchymatous degeneration—Fatty metamorphosis—Mucoid and colloid degenerations—Amyloid or waxy degeneration—Calcareous degeneration—Pigmentation.

Infiltrations and Degenerations.

THE remaining passive alterations of the tissues or regressive metamorphoses may be divided, theoretically, into the *infiltrations* and the *degenerations*. Infiltration is a term ordinarily applied to the deposition of some material in or between the tissue-elements. In degeneration there is a metamorphosis of cell-substance into new material. Our knowledge, however, does not yet suffice to enable us to carry out strictly this distinction. The terms infiltration and degeneration, therefore, will sometimes be applied to processes, the nature of which is not thoroughly understood, and the propriety of designating which as infiltration or as degeneration is not established.

Parenchymatous Degeneration—Cloudy Swelling.

The names parenchymatous degeneration or inflammation, albuminous infiltration, granular degeneration, and cloudy swelling are used as synonyms for the same metamorphosis. This change consists in the appearance in cells and sometimes in intercellular substance of numerous albuminous granules. Especially subject to this alteration are the muscular fibres and the parenchymatous cells of the glandular organs, particularly the renal epithelium, the hepatic cells, and the peptic cells. The affected parts appear swollen, opaque, as if boiled, according to Virchow's comparison, and the normal markings, as of the hepatic acini and of the renal striæ, appear obscured. The microscopical examination shows the cells swollen and filled with fine granules which dissolve in acetic acid and in potash. In the kidney, the epithelium of the convoluted tubes, and in the liver, the hepatic cells, are normally so granular that the macroscopical appearances are more conclusive as to the existence of this change than the microscopical. The muscular fibres of the heart are prone to this change. They then contain albuminous molecules which obscure the normal striation. The cells in inflamed parts undergo parenchymatous degeneration. Of the general causes may be mentioned infectious diseases, such as

typhus and typhoid fever, pyæmia, puerperal fever, diphtheria, and poisoning with phosphorus, arsenic, or the mineral acids. Cloudy swelling has been developed within six hours after extensive burns (E. Wagner). The view of Liebermeister that it is solely the influence of high temperature in general diseases which causes this metamorphosis, has been abundantly disproven. Cloudy swelling is sometimes followed by fatty degeneration. If its causes disappear, there is usually a return to the normal condition. Parenchymatous degeneration undoubtedly impairs the function of the affected parts.

Fatty Metamorphosis.

The fat in the body is derived, on the one hand, from oleaginous articles of diet, and, on the other hand, from the transformation of albuminous constituents either of the food or of cells. The carbohydrates favor the accumulation of fat by preventing its oxidation, not by directly producing it. There are certain natural reservoirs or dêpots for the physiological accumulation of fat. Of these, the most important are the connective tissue in certain parts of the body, particularly adipose tissue, also the marrow of bone, the liver, the sebaceous glands, and during lactation the mammary gland. In these parts, especially in the liver, it is often difficult to distinguish between a normal and an abnormal deposition of fat. Under pathological conditions, fat may appear in situations where it does not normally exist, for instance, in muscular fibres. Under normal and pathological conditions the fat is deposited chiefly within the protoplasm of cells. It is customary to distinguish between *fatty infiltration* and *fatty degeneration*. In fatty infiltration, or fatty growth, the fat has been believed to come from without the cells, and to infiltrate them in the form of large drops, and in fatty degeneration to be derived by direct metamorphosis from the cell-substance, and to appear in the form of molecules. But these distinctions cannot be maintained. Thus, in so-called fatty infiltration, while the fat may be derived from without, it is equally certain that it may be produced directly from the protoplasm of the cells. Thus, no one would consider the drops of oil so frequently found in growing cartilage-cells as evidence of fatty degeneration; still, the fat here can hardly be formed otherwise than from the substance of the cells. Again, there can be no purer example of fatty infiltration than the absorption of fat by the intestinal epithelium, in which, however, the fat appears in the form of fine granules. Most writers consider the fatty liver resulting from poisoning by phosphorus as an instance of fatty degeneration, although here the fat appears as large drops. The chief distinction between fatty infiltration and fatty degeneration, to continue to use the old terms, is more chemical than morphological. In fatty infiltration of a cell, the protoplasm is displaced by the fat, but does not suffer materially in its integrity except by a slow process of atrophy from compression; if the fat be derived from the albuminous constituents of the cell, these are, in great part at least, renewed. In fatty degeneration, on the other hand, the cell-substance is directly converted into fat, and is not at all, or only insufficiently, regenerated. Hence fatty degeneration is also called fatty atrophy. A considerable degree of fatty infiltration may exist without interfering materially with the function of the affected cells, although, in extreme degrees, this must suffer. But fatty degeneration is a much more destructive process, and interferes, to a much greater extent, with the function of the cells. From the examinations of Perls[1] it appears that in fatty infiltration the fat is deposited especially at the expense of the water of the tissues, and in fatty degeneration at the expense of the solid

[1] Perls, Lehrbuch der allgemein. Pathologie, Theil I., p. 172, 1877.

constituents. In fatty infiltration the amount of fat is generally much greater than in fatty degeneration. Inasmuch as the chemical examination is rarely practicable, and as the supposed histological criteria are often fallacious, it is not always possible to draw a sharp line of distinction between fatty infiltration and fatty degeneration. The problems involved are certainly more complex than was formerly believed.

In determining the nature of the process, it is of the greatest importance to take cognizance of the cause. The accumulation of fat in the organism is always the result of its incomplete oxidation. The causes of fatty metamorphosis, therefore, are, *first*, excessive supply or excessive formation of fat, and *second*, diminished oxidation of the fat.

Too abundant ingestion of rich food, especially of fat and of carbohydrates, leads to *obesity* or the excessive accumulation of fat in its natural dêpots. Constitutional peculiarities, often hereditary, the nature of which is not understood, favor the development of corpulence. An excessive formation of fat seems to be sometimes the result of increased nutritive activity, as in growing cells. The causes leading to diminished oxidation of the fat may be general or local. The general causes are, *first*, interference with the absorption of oxygen in consequence of disease of the respiratory organs; *second*, diminution of the hæmoglobin of the blood, and *third*, agencies which check the normal oxidizing processes. Diseases of the respiratory organs, in themselves, rarely, if ever, lead to fatty metamorphosis, but they increase the efficiency of other causes. The various agencies which diminish the number, or impair the quality, of the red blood-corpuscles, these being the carriers of oxygen, are important causes of fatty degeneration. In this group of causes are to be reckoned progressive pernicious anæmia, icterus gravis, and other diseases attended by profound anæmia, as leucocythæmia, chlorosis, chronic pulmonary tuberculosis, and in less degree other chronic cachexiæ. Phosphorus and some other poisons lead to destruction of the red blood-corpuscles and consequent fatty metamorphoses. There is some reason to believe that an insufficient supply of oxygen favors rapid tissue metamorphosis with the formation of fat. Especially in phosphorus-poisoning does there seem to be an excessive formation of fat as well as diminished oxidation. The use of alcohol favors the accumulation of fat by diminishing its normal oxidation. The parts which are most subject to fatty degeneration from general causes are, the liver, the kidneys, the muscles, especially the cardiac muscle, and the coats of the small arteries.

Local fatty degeneration can be attributed generally to an insufficient supply of oxygenated blood. It is to be remembered that complete cessation of the blood-current leads to necrosis, and not to fatty degeneration. In cirrhotic livers the hepatic cells are often fatty from the interference with the circulation through the organ. Pus-cells are usually fatty from imperfect nutrition. For the same reason other inflammatory exudations undergo fatty degeneration. The opaque ring so often observed in the outer margin of the cornea of old people and called *arcus senilis*, is due to fatty degeneration of the corneal corpuscles.

A fatty organ is generally anæmic, of a yellowish color, and of diminished consistence. In fatty degeneration of muscles, the fibres contain numerous molecules and small drops of oil; the striæ are obscured and may disappear. In the fatty infiltration of muscles, the fat is deposited always in large drops in the cells of the interstitial tissue, and not in the muscular fibres. In fatty degeneration the cells may be completely destroyed, leaving only a fatty detritus. The description of the gross and microscopical appearances in the fatty metamorphosis of different organs belongs to Part II. of this work, where especially the sections devoted to fatty heart and to fatty liver may be consulted.

Mucoid and Colloid Degenerations.

Mucoid degeneration consists in the transformation of the albuminous constituents of cells or of intercellular substance into mucin which gives the tissues a gelatinous, translucent appearance. Mucin is an albuminoid substance devoid of sulphur, only held in solution by an alkali, and, therefore, precipitated by acetic acid, in excess of which it is insoluble. It is normally secreted by epithelial cells of mucous membrane, also of certain glands, and it is widely distributed in the embryonic tissues. Pathologically, mucin may appear in abnormal amount in consequence of excessive metamorphosis in the epithelial cells which secrete it, but it may also be the result of mucoid transformation of the intercellular substance. The mucoid change occurs occasionally in cartilage, the marrow of bone, and especially in tumors. In the myxomata the intercellular tissue is composed chiefly of a substance containing mucin.

The *colloid metamorphosis* is allied to the mucoid. It affects chiefly cells. The colloid material appears in the form of drops either free or within cells, and it may appear more diffusely. It is of firmer consistence than mucin, contains sulphur, and is not precipitated by acetic acid. In its gelatinous, homogeneous appearance it resembles mucin. The colloid material accumulates in great amount in the follicles of the thyroid gland in goitre. The colloid change may also affect the cells in tumors. Colloid cancer has already been described.

In ovarian cysts, a viscid, gelatinous substance appears called *paralbumen* which is regarded as a secretion of the lining epithelium. This paralbumen is precipitated by dilute acetic acid, but is soluble in an excess of the acid.

The causes of these metamorphoses are not understood.

A *hyaline transformation* of the walls of the small bloodvessels has been observed in various organs of the body, particularly in the brain, lymphatic glands, and ovary. The hyaline material is homogeneous and resembles the waxy deposit but does not give its reactions. The cause and pathological significance of this degeneration are not known.

Amyloid or Waxy Degeneration.

The degeneration called waxy, amyloid, or lardaceous, is characterized by the appearance, especially in the walls of the vessels, but also elsewhere, of a homogeneous, firm, inelastic, translucent substance similar in its composition to the albuminous matters, but more resistant to putrefaction and to the action of the gastric juice. The most important property of this new substance is its reaction with certain coloring agents which are therefore employed for its detection. Treated with iodine, it is stained mahogany-brown; with iodine and sulphuric acid, blue; and with methyl-violet, red. The substance was called amyloid from its supposed resemblance to starch, but it is now known to be a nitrogenous substance. For detecting the amyloid degeneration with the naked eye, a solution of iodine alone (Lugol's solution) is most applicable. The waxy degeneration may be local, but it generally affects a number of organs. The parts most frequently involved are the spleen, liver, kidneys, lymphatic glands, and the intestinal mucous membrane. Other parts may be affected, as the large vessels, the heart-muscle, the supra-renal capsules, and the small vessels in most organs. If the degeneration be well marked, the affected part presents a characteristic, translucent, grayish appearance, and is usually more or less swollen. The waxy material is exceptionally deposited in large nodules, constituting the waxy tumors. As a rule, the degeneration appears first in the walls of the small arteries and about the capillaries; thence it may extend to the surrounding tissue, which in some cases appears

to be primarily involved. It has usually been held that a waxy degeneration may invade cells, connective tissue, and, in fact, nearly all the histological elements. Some recent investigators, however, hold that it is confined chiefly to connective tissue, attacking first that of the intima and media of the small arteries and that about the capillaries, extending thence to the interstitial tissue. The so-called structureless membranes, such as the membrana propria of the uriniferous tubules, may undergo the change. The waxy substance is often deposited in irregular clumps. The cells are compressed and atrophied. According to Eberth, they do not themselves undergo the waxy change. Kyber, in his latest investigations, however, finds that the parenchymatous cells of the liver and spleen become waxy. The vascular walls become converted into a hyaline, swollen mass which encroaches upon the lumen. The endothelium is for a long time preserved, and the circulation continues until the vessel is nearly obliterated. Further investigations are needed to determine precisely the anatomical elements involved in the degeneration, as the statements of different writers are discrepant respecting this point. The anatomical peculiarities presented in the amyloid degeneration of different organs will be described in Part II.

The causes of waxy degeneration are, chronic suppurations, particularly of bone, and certain cachexiæ, especially the syphilitic, the tuberculous, and, in a less degree, the cancerous, the gouty, and the malarial. In rare instances no apparent cause can be assigned. The degeneration may be developed within a few months from the onset of suppurative processes. It appears, as a rule, first in the spleen. It is difficult to tell exactly what symptoms are referable to waxy degeneration, as it is associated with severe wasting diseases. In the kidneys it seems to be always associated with more or less change in the interstitial tissue and in the epithelium. Waxy degeneration of the intestines leads to chronic diarrhœa.

The source of the waxy material is not known, whether from the blood or from the albuminous substances in the tissues. The theory of Dickinson, that amyloid material is dealkalized fibrin, the alkali having been drained away by chronic suppuration, must be difficult to prove.

There appear in various parts of the body, both normally and pathologically, spherical or irregular masses, which usually present a concentric arrangement, and which are called *corpora amylacea*. They often assume a blue color when treated with iodine, or with iodine and sulphuric acid. They are not known to have any relation to waxy degeneration. So far as ascertained, they have no pathological importance. They occur especially in the prostate gland and in the central nervous system, in the latter being particularly numerous in chronic inflammatory processes.

Calcareous Degeneration.

An infiltration of the tissues with the phosphate and carbonate of lime, mingled usually with the same magnesia salts, constitutes what is called *calcareous degeneration*, *calcification*, or *cretefaction*. This change is not to be confounded with *ossification*, although the latter term is often applied to it erroneously. In ossification there is a formation of true bone. In calcification the salts of lime are deposited at first in the form of irregularly scattered granules which appear dark by transmitted, and bright by reflected, light. Large calcareous masses may be formed by increase in number and size of the granules. Calcified tissues are recognized by their hard, sometimes stony, consistence, and by the solubility of the earthy salts in strong acids, usually with the evolution of bubbles of gas. The salts are deposited chiefly in the intercellular substance, but the cells may also become infiltrated.

The causes of calcification are, *first*, excessive quantity of earthy salts in the fluids of the body; *second*, diminution of agents which normally hold in solution the salts of lime, particularly of free carbonic acid; and *third*, transformation of soluble lime-salts into insoluble modifications.

Virchow has described, under the designation *lime-metastases*, the deposit of the salts of lime in various parts of the body, particularly in the arteries, lungs, and stomach, in cases of extensive caries and of cancerous disease of bone. This calcification he attributes to the presence in the blood of an absolute excess of lime-salts derived by absorption from the diseased bone. With the exception of these cases to which Virchow has called attention, it does not appear that calcareous degeneration can be referred to an abnormal amount of lime in the blood.

The other causes of calcification are believed to be operative when the salts of lime are locally deposited in tissues, the nutrition of which is impaired. In the vast majority of cases, lime is deposited in tissues previously diseased. Especially prone to calcification are tissues which have undergone fatty degeneration or coagulation-necrosis as the result of anæmia. Thus, Litten observed calcareous particles in renal epithelial cells, in which coagulation-necrosis had developed, in twenty-four hours after temporary ligation of the renal artery. We find calcific deposits in cheesy masses, in old inflammatory products, desiccated pus, in tumors, and in and about parasites. Of great practical importance are the calcification of the cardiac valves in chronic endocarditis, and that of the arteries either with or without inflammatory changes. Calcification of the internal and middle coats of the arteries belongs among the usual changes in old age. What is usually called calcification of cartilage is ossification or a change preparatory to ossification. Calcification may be a conservative process, as when it checks the growth of tumors, or it may be detrimental, as when it affects the arteries or cardiac valves.

Pigmentation.

The colors of the pigments found in the body are usually some shades of yellow, red, brown, or black. Pigmentation is not in itself a morbid process of much importance, but it may be significant as an evidence of old hemorrhage. The most important, although not the sole, source of the pathological pigments, is the coloring matter of the blood. The hæmoglobin of extravasated red blood-corpuscles may be converted into yellow or brown pigment-granules, or into red rhombic crystals called hæmatoidin. The granular pigment, although also called hæmatoidin, contains iron which is absent in crystalline hæmatoidin. According to Langhans, the transformation into hæmatoidin occurs, not from diffused blood-coloring matter, but from red blood-corpuscles or their fragments. They are taken up by cells, especially leucocytes, in which the metamorphosis into granular or crystalline pigment takes place. The pigment may subsequently be set free from the cells. The yellowish-brown pigment-granules in the blood and in various organs in the melanæmia of severe malarial intoxication, are derived from the destruction of red blood-corpuscles. Bilirubin-crystals, which are derived from bile-pigment, and are sometimes found in the liver and kidney in cases of icterus, are identical in appearance, and probably in composition, with hæmatoidin-crystals. Melanin is a name which embraces most of the black pigments formed in the body without regard to their origin. Some of them are derived from the blood coloring-matter. The black pigment always present in the lungs of adults consists of inhaled particles of carbon. When this black pigmentation is excessive, as is often the case in coal-miners' lungs, the term anthracosis is applied to the morbid condition. Fatty molecules are sometimes

deeply stained with yellow or brown pigment, the source of which is not known. Pigment-granules in corpora lutea, in the muscular fibres in brown atrophy of the heart, and in part those frequently present in the walls of the cerebral vessels, are composed of colored particles of fat. It is probable that pigment may be elaborated by the protoplasm of cells. This appears to be the source in most melanotic tumors, in freckles, chloasma, and of the physiological pigment in the choroid coat of the eye and in the rete Malpighi of negroes.

CHAPTER VI.

GENERAL PATHOLOGY OF THE BLOOD.

Plethora—Anæmia—Hydræmia—Anhydræmia—Hyperinosis—Hypinosis—Leucocytosis—Alterations in the gases of the blood—Increase of oxygen—Effects of breathing compressed air—Deficiency of oxygen—Apnœa—Changes in the albumen, fat, and inorganic salts.

THE morbid conditions to be now considered embrace alterations in the quantity or in the quality of the entire mass of the blood. The means for regulating the composition of the blood in health are such that the mass of the blood is easily kept within physiological limits, notwithstanding changes in diet and in physical surroundings. Disturbances of this physiological regulation are generally referable to morbid processes in the solids, and hence the changes embraced in the general pathology of the blood are not independent affections of the blood itself, as they were regarded by the humoral pathologists, but they result usually from disease of the solid tissues, including the blood-forming organs. There are some alterations of the blood in which this connection has not been traced, and, without doubt, morbific agents may exercise their injurious influence primarily upon the blood as well as upon other tissues, for the blood may be regarded as a tissue with cells and fluid intercellular substance. The so-called *dyscrasiæ* depend upon anomalies in the composition of the blood of a chronic nature, and usually, if not always, are secondary to diseases of the solid parts. The physiological relations of the blood to the solid parts are so intimate and important as to render it intelligible that morbid alterations in its composition lead secondarily to changes in the solids, as well as that diseases of the solids affect the composition of the blood.

Alterations in the blood may affect, severally or combined, the corpuscular elements, the water, the organic ingredients of the plasma, namely, albumen and fibrin-generators, the gases, and the inorganic salts. Morbid conditions of the blood, due to the introduction of substances not entering into its normal composition, are also to be included in the consideration of its general pathology.

Plethora.

Plethora signifies an increase either in the total amount of the blood or in the number of the red blood-corpuscles beyond the healthy limit. The former of these conditions constitutes *polyæmia*, the latter *polycythæmia*. Indi-

viduals with a certain group of symptoms have, since remote times, been designated as plethoric, upon the assumption that the symptoms were due to an excess of blood. The symptoms referred to are abnormal redness of the face and mucous membranes, fulness of the pulse, increase of the heart's impulse, with tendency to palpitations, a sensation of warmth and of fulness, especially in the head and chest, sometimes epistaxis and hemorrhages from different mucous membranes. Constitutional tendency, overfeeding, idleness and luxurious habits, and the arrest of periodical or habitual hemorrhages are the leading causes assigned for this condition of supposed plethora. Blood-letting, reduced diet, and increased exercise often relieve the symptoms. While the symptoms and the means of relief certainly suggest an excess of blood, yet an increase in the amount of blood or of red blood-corpuscles in this condition has not been proven, and recent experiments on animals render improbable the existence of a permanent polyæmia.

Temporary plethora may be produced by *transfusion* of blood from one animal into another of the same species. In this way the amount of blood in a dog may be doubled without evident discomfort to the animal after the injection, and with only a brief rise in the blood-pressure during the operation. It is thus shown that the bloodvessels are capable of holding much more than the normal amount of blood. It is an interesting fact, however, that the transfusion of this large amount impairs so much the elasticity of the vessels that they cannot at once accommodate themselves even to the normal quantity of blood, and the animal dies upon the immediate withdrawal of an amount of blood even less than that injected. Within a few hours after the transfusion, the quantity of blood-plasma is considerably lessened, and after two or three days it returns to the normal amount. This reduction is effected chiefly by increase in the urinary secretion. The excess in red blood-corpuscles persists somewhat longer. A true polycythæmia exists. But in a few days, at the most in from two to four weeks, the number of red blood-corpuscles is also reduced to the normal quantity. This destruction of red blood-corpuscles is indicated by increased excretion of urea. If blood be injected equal in amount to 150 per cent. of the total quantity of blood in the animal, death ensues with symptoms of exhaustion, vomiting, and hæmaturia.

If the blood of one species of animal be injected into that of another species, the effects are entirely different. If by transfusion of lamb's blood into the veins of a dog the quantity be increased only one-fifth, the death of the dog ensues, as a rule, on the first or second day. Even half of that quantity produces severe symptoms, especially hæmoglobinuria and a general tendency to hemorrhages. The injurious effects of the transfusion of foreign blood may be explained, in part, by the fact that the serum of the blood of certain species dissolves the red corpuscles of other species.

It has been discovered by Köhler[1] that the injection into the jugular vein of a small quantity of serum rendered rich in fibrin-ferment by spontaneous coagulation of the blood, and subsequently straining through linen, causes often, although not invariably, the rapid death of the animal from coagulation of the blood in the right cavities of the heart, the pulmonary artery and its branches. The transfusion of blood which has been defibrinated by stirring, does not produce these harmful effects.

It is apparent that these experiments on animals throw much doubt upon the existence of true plethora in man, without absolutely disproving the possibility of its occurrence as a permanent condition. There is certainly no proof that the symptoms hitherto embraced under the name plethora depend upon either polyæmia or polycythæmia. It has been suggested that their

[1] Köhler, Ueber Thrombose u. Transfusion, Dorpat, 1877.

cause is to be found in impaired function of the vaso-motor nerves, the regulators of the circulation.

Anæmia.

Local anæmia or ischæmia dependent upon local disturbances of the circulation, has been already described (*vide* page 26). Under the name general anæmia are included diminution in the mass of blood or *oligæmia*, diminution in the number of red blood-corpuscles or *oligocythæmia*, and diminution in the amount of hæmoglobin in the red blood-corpuscles or *achroiocythæmia*. In many cases of anæmia some of the red corpuscles are much reduced in size. These small corpuscles are called *microcytes*, and the condition of the blood containing them is called *microcythæmia*. These microcytes are regarded by some as red blood-corpuscles in process of formation, by others as atrophied or degenerated red corpuscles. *Hydræmia* or diminution of the solid ingredients of the plasma, especially the albumen, is also an element in most forms of anæmia. But the essential element in anæmia is diminution in the hæmoglobin of the blood. It is to this loss of the coloring matter of the blood that the most obvious and characteristic symptom of anæmia, namely, the pallor, is due. It was formerly believed that the quantity of hæmoglobin in the blood is directly proportional to the number of red blood-corpuscles, but recent observations have shown that red blood-corpuscles in disease vary in the percentage of hæmoglobin which they contain, so that reduction in the amount of hæmoglobin in the blood does not necessarily involve a corresponding diminution in the number of red corpuscles. Still, a greater or less loss of red blood-corpuscles is an almost constant change in anæmia, and the cases are exceptional in which the extent of this loss is not an approximately correct index of the degree of anæmia.

In anæmia, therefore, we may have changes in the *quality* as well as in the *quantity* of red blood-corpuscles. The only change in quality with which we are familiar is diminution in the amount of the hæmoglobin in individual corpuscles. This fact may be determined by observing the relation which exists between the number of red corpuscles and the percentage of hæmoglobin in the blood. It may also be inferred when the red corpuscles have an abnormally pale color. When the blood contains many of these pale corpuscles, as is often the case in chlorosis, the condition is called achroiocythæmia or oligochromæmia. The means for estimating the number of red blood-corpuscles and for determining the percentage of hæmoglobin have been greatly improved within the last few years. By the methods of Melassez and of Hayem the number of red corpuscles in a cubic millimetre of blood is estimated at five millions in health. This number in anæmia is often reduced one-half, and in cases of extreme anæmia it may fall as low as half a million, which seems to be about the lowest limit compatible with life. The average diameter of the human red corpuscles in health is between seven and eight micromillimetres. There may be in health corpuscles much smaller than this, and some larger than the average. But in anæmia there is often a large number of corpuscles called microcytes, whose size is between two and six micromillimetres, and, on the other hand, there may be some corpuscles measuring twelve to fourteen micromillimetres in diameter. The shape of these corpuscles may also deviate from that of the normal biconcave disks with round contours. The name *poikilocytosis* has been proposed to designate the condition of blood in which the corpuscles present manifold variations in shape. The normal amount of hæmoglobin (oxyhæmoglobin) in the blood is estimated at from 12 to 14 per cent. This amount may be reduced in anæmia even as low as to 2 per cent. Cases of chlorosis have been observed with the

normal number of red corpuscles, and with less than half the proper amount of hæmoglobin (achroiocythæmia). The total mass of blood is not necessarily reduced in anæmia out of proportion to the loss of weight of the body, except in cases of acute anæmia immediately following hemorrhage. It may, however, be disproportionately lessened. In two cases of progressive pernicious anæmia reported by Quincke,[1] the quantity of blood was estimated to be 4 to 5 per cent. of the weight of the body, instead of 8 per cent., the normal proportion.

If the anæmia be severe and chronic, there are produced secondary changes in the organs and tissues of the body. Of these changes none is more important or more characteristic than fatty degeneration of the heart, as has been emphasized especially by Ponfick. Fatty degeneration of the walls of the vessels, of the liver, the kidneys, and sometimes of the voluntary muscles, may also be induced, but in less degree. Ecchymoses and a hemorrhagic diathesis may be the result of profound anæmia. Atrophy of different organs of the body is a natural result of long-continued anæmia. The nervous centres suffer the least in their nutrition. An interesting change in the marrow of the bones has been observed in profound, chronic anæmia, and is probably to be regarded as secondary. This change consists in the appearance of red, in the place of the yellow, medulla which is normally present in the long bones of adults. The fat disappears, the number of medullary cells is greatly increased, and a considerable number of nucleated red blood-corpuscles make their appearance. This alteration is a return of the yellow marrow to the condition it presents in fœtal and infantile life. Some think that this change in the osseous medulla has to do with the regeneration of red blood-corpuscles.

Although it has long been known that if the cause of anæmia be removed the red corpuscles are renewed in a comparatively short time, we possess little positive knowledge as to the mode of regeneration. Experiment and pathological observation point especially to the spleen and marrow of the bones, perhaps also to the lymphatic glands, as organs in which red as well as white blood-corpuscles may be formed. The weight of evidence is in favor of the view that red corpuscles are formed in some way out of white corpuscles or their equivalents. Recently especial importance has been attributed to the nucleated red blood-corpuscles which are found in anæmia, often in considerable number, in the marrow of the bones, in the spleen, and in scanty number in the blood. These same corpuscles are abundant in the red marrow of infants, and may be found here and there, according to Neumann, even in the yellow marrow of adults. They resemble in all particulars the nucleated red corpuscles in the blood of young embryos. According to Rindfleisch,[2] they are transformed into the ordinary non-nucleated red blood-corpuscles by extrusion of the nucleus. According to this pathologist, they are capable of proliferation, and, when the process of division is active, the daughter cells are smaller than ordinary blood-corpuscles. These nucleated red blood-corpuscles are considered by Bizzozero and Rindfleisch to represent transitional forms between white and red corpuscles, but the phases of this metamorphosis are as yet imperfectly known. Hayem,[3] who has written elaborately upon the formation of red corpuscles, maintains that certain small granules and corpuscles, especially abundant in the blood of certain anæmic individuals, and, in part at least, hitherto known as elementary granules and microcytes, represent developing red blood-corpuscles, and are, therefore, to be called *hæmatoblasts*.

[1] Quincke, Deutsches Archiv f. klin. Med., Bd. 21. p. 27, 1877.
[2] Rindfleisch, Archiv für microscopische Anatomie, 1879.
[3] Hayem, Archives de Physiologie norm. et path., 1878–9.

Although Rindfleisch suggests that Hayem's microcytes may be young daughter-cells derived from rapidly proliferating nucleated red corpuscles, there seems to be little resemblance between the views of Hayem and those of Neumann and Rindfleisch.

Anæmia may be divided into acute and chronic. The best example of acute anæmia is that produced by copious hemorrhages. This also affords the purest example of oligæmia. A considerable amount of blood, in dogs over one-quarter of the entire mass, may be withdrawn from healthy individuals without permanent damage. The loss of one-half of the entire volume of blood is usually fatal. Females, as a rule, are more tolerant of loss of blood than males. Infants are especially susceptible to the evil effects of the withdrawal of blood. A large quantity of blood, in dogs over a quarter of the whole volume, may be removed without more than a temporary lowering of the blood-pressure. Under the influence of the vaso-motor nerves, which are affected by anæmia as by an irritant, the vessels adapt themselves within very wide limits to varying amounts of blood without permanent alteration of the blood-pressure. In healthy individuals a very considerable loss of blood is repaired within a short time, at the most in three or four weeks. The blood is very soon restored to its normal volume by the absorption of water. As the red blood-corpuscles and the albumen are not so easily renewed, the specific gravity of the blood is now diminished. A condition of hydræmia has replaced the oligæmia. The white blood-corpuscles are sooner restored than the red. There are fewer white than red corpuscles in proportion to the number lost by hemorrhage. The former are of less weight, more viscid, and do not so readily escape from the vessels. Then the lymph, the flow of which is increased by severe hemorrhages, constantly brings new leucocytes to the blood, so that soon after a considerable hemorrhage the number of white corpuscles, in proportion to the red, is increased. A temporary relative leucocytosis is thus produced. The food restores to the blood its normal amount of albumen. The red blood-corpuscles are also regenerated, although more slowly.

The symptoms of acute anæmia are of course grave in proportion to the amount of blood lost. They are weakness, pallor, coldness of the surface, feeble and rapid pulse, dimness of vision, dyspnœa, muscular spasms, especially in the calves of the legs, and, if the loss of blood be sufficient, unconsciousness and epileptiform convulsions from anæmia of the brain. The symptoms are more marked when the hemorrhage occurs in persons previously healthy than in those already enfeebled. The immediate treatment consists in means to arrest the hemorrhage, in maintenance of the recumbent posture, with the head lower than the feet, in the administration of stimulants, and, if necessary, in the transfusion of blood.

The most important causes of chronic anæmia are the following: 1, repeated hemorrhages, as menorrhagia, hæmatemesis; 2, the loss of essential constituents of the plasma, particularly albumen, as in chronic albuminuria, prolonged lactation, chronic dysentery and diarrhœa, prolonged suppurations; 3, defective supply of nutriment (anæmia of inanition); 4, affections occasioning indigestion and vomiting, as chronic gastritis, ulcer of the stomach; 5, chronic wasting diseases, particularly tuberculosis and cancer; 6, the poisons of chronic infectious diseases, as malaria, syphilis; 7, certain mineral poisons, especially lead and mercury. Anæmia, more acute in its development, may attend acute infectious diseases, as yellow fever, typhoid fever, and the entrance into the blood of poisons which rapidly destroy the red corpuscles, as phosphorus and the biliary salts. There is further an important class of anæmias for which, with our present knowledge, no cause can be assigned. This class embraces leucocythæmia, pseudo-leucocythæmia, Addison's disease, chlorosis,

and progressive pernicious anæmia. Profound and often fatal anæmia, without apparent cause or obvious structural changes in the body, exclusive of those which may be secondary to the anæmia, is known as idiopathic, essential or pernicious anæmia. The most reasonable hypothesis as to these anæmias without known cause is, that they depend upon disturbances in the blood-forming organs, which may be embraced under the generic name hæmatopoietic system. As these forms of anæmia constitute, for the most part, well-defined diseases, susceptible usually of diagnosis, it will be convenient to treat them in Part II. of this work, under the heading, Diseases of the Hæmatopoietic System, although, as has already been stated, our knowledge of the formation of blood-corpuscles after birth is incomplete.

As is evident from the enumeration of its causes, symptomatic anæmia is incident to a variety of diseases, in connection with which it will hereafter be referred to. It is proper here to mention the common and most diagnostic symptoms, although they may be modified by the primary disease. Such symptoms are pallor of the face and mucous membranes, impairment of muscular and mental energy, functional disorders of the nervous system, especially neuralgia and so-called spinal irritation, coldness of the surface, dyspnœa on exertion, impaired digestion, palpitation of the heart, a pulse either small or full, but compressible. It is important to note that in persons who have an unusual vascularity of the face, anæmia may exist not only without notable pallor, but even with a rosy complexion. Of especial importance in the diagnosis of anæmia is the presence of certain physical signs. There is often present in anæmia a soft bellows-murmur accompanying the first sound of the heart, and heard most distinctly at the base of the heart and in the larger arteries, the carotid, the subclavian, etc. To constitute evidence of anæmia there must be wanting the signs of organic lesion of the heart and large vessels. In conjunction with this murmur, a continuous humming sound, sometimes musical, is heard when the stethoscope is applied over the veins of the neck. This sound, due to the movement of blood in the veins, is called the venous hum, or, after the French, *bruit de diable*. These murmurs are distinguished from those denoting lesions, as inorganic, hæmic, or anæmic murmurs. The arterial murmur is present in only a certain proportion of cases, but the venous hum may be heard almost invariably.

Symptomatic anæmia is sometimes amenable to treatment, at other times not, according to the nature of the primary disease. It may be noted that anæmia is not incompatible with embonpoint. The first indication is to ascertain and remove if possible the cause or causes on which the anæmia depends. The most important measures in restoring the quality and quantity of red globules are, *first*, a nutritious alimentation into which meat should enter largely; *second*, iron as a special remedy, the effect of which in increasing the amount of hæmoglobin and the number of corpuscles is often remarkable; *third*, other tonics, as arsenic, quinine, strychnine, and stimulants to render the digestive functions more active; and *fourth*, a regimen calculated to increase the energy of the assimilative functions, consisting in exercise in the open air, change of climate, recreation, etc.

Hydræmia.

By *hydræmia* is understood a relative or an absolute increase in the amount of water in the blood in proportion to the solid ingredients. It is the diminution in the amount of albumen which forms the chief element in hydræmia. Less emphasis is laid in this connection upon the loss of blood-corpuscles, although, as has been mentioned already, anæmia and hydræmia are usually associated. The salts and extractive matters of the blood are left out of con-

sideration. Hydræmia is essentially hypalbuminosis, relative or absolute. There are three possible forms of hydræmia: in the *first* the amount of water is normal, but the solids are diminished; in the *second* the solids are normal in quantity, but the amount of water is increased; in the *third* the amount of solids is diminished, and that of the water is increased. In the third form the highest degree of hydræmia is reached. The various causes of anæmia, involving loss of the solid constituents of the blood, are also causes of hydræmia. The most extreme hydræmia is that produced in many cases of chronic nephritis or Bright's disease, in which there is not only a continual drain of albumen from the blood, but the excretion of water by the kidneys is lessened. The conditions are here present for the production of the third form of hydræmia. In Bright's disease the specific gravity of the blood-serum has been known to sink from 1030 to 1013, the percentage of albumen from 8 to 4 per cent., corresponding to an increase in the amount of water from 90 to 95 per cent. General œdema has long been considered to be a most characteristic symptom of hydræmia. The abundant serous transudations in various parts of the body in Bright's disease, have been referred directly to the extreme hydræmia of this disease. It was naturally supposed that the less concentrated the plasma, the more readily it would transude through the walls of the vessels. The experiments of Cohnheim and Lichtheim,[1] however, have demonstrated that hydræmia, even when present in a degree never met with in man, is not a direct cause of general œdema, but that this œdema follows only when the nutrition of the vascular walls is impaired and they are thereby rendered more permeable. Inasmuch, however, as the hydræmia favors this weakening of the vessel-walls, it still must be considered an important indirect cause of anasarca. Cohnheim and Lichtheim produced hydræmia in dogs and other animals by injecting into the blood a watery solution of common salt of the strength of 0.6–0.75 per cent. If they induced a simple hydræmia by withdrawing a certain quantity of blood and injecting an equal quantity of the salt solution, they observed no œdema nor increased flow of lymph in any part of the body. The results were different when they produced hydræmic plethora. They found it possible to inject a much larger quantity of salt solution than of blood. Whereas the life of the animal was endangered by transfusing one and a half times the normal quantity of blood, complete recovery followed after injecting of the salt-solution a quantity equal to three times the normal volume of blood. In fact, it was not unusual to inject a quantity of the salt-solution equal to 60–70 per cent. of the weight of the body (the normal amount of blood equals 8 per cent.) before the death of the animal resulted. After the transfusion of this enormous amount of fluid, they found the velocity of the blood-current increased, but the arterial pressure little, if at all, elevated. The excess of fluid did not, of course, remain long within the vessels, but, with the exception of ascites, there was no œdema in the situations in which it usually occurs in man. All of the secretions were increased, the urine, the intestinal transudations, the bile, the saliva. There was also more or less extensive serous transudation in and about the organs of secretion, namely, the salivary glands, the pancreas, the liver, the kidneys, the walls of the stomach and intestines, the peritoneum. The flow of lymph from the abdominal viscera was greatly increased. On the other hand, in the extremities the flow of lymph was not increased, nor was any œdema induced if the vessels were normal. If, however, the skin of the legs or that of any other part of the body had been previously rubbed with croton-oil so as to excite inflammatory changes in the vascular walls, then œdema resulted in the altered parts. As the œdema produced by hydræmic plethora

[1] Cohnheim and Lichtheim, Virchow's Archiv, Bd. 69, p. 106.

occurs chiefly in and about secretory organs, as true plethora produced by transfusing a large quantity of blood is accompanied by extravasations and moderate transudations in the same situations, and as simple hydræmia is not attended by increased transudation anywhere, Cohnheim and Lichtheim attribute the transudations of artificial hydræmic plethora, less to the watery state of the blood, than to the increased volume of blood. It is certain that in man we never have to do with hydræmic plethora comparable in degree with that which Cohnheim and Litten succeeded in producing in animals.

While then hydræmia can no longer be considered an immediate cause of œdema, it nevertheless is of importance in the etiology of serous transudations which it favors in two ways: *first*, by inducing nutritive changes in the vessel-walls, thereby increasing their permeability; *second*, by facilitating transudation when from any cause the walls of the vessels are impaired. There is reason to believe that in most forms of Bright's disease the walls of the vessels in the skin and in various other parts of the body are impaired, partly as an element in the disease, partly as the result of hydræmia and altered composition of the blood.

Anhydræmia.

A too concentrated state of the blood in consequence of an absolute increase in its solid constituents, is not a recognized pathological condition. We know nothing of absolute *hyperalbuminosis* as a morbid state of the blood. *Anhydræmia*, or a thickened condition of the blood from loss of water, is familiar to us in man only as a change resulting from excessive serous discharges from the intestine, particularly as a result of cholera. In cholera the blood may become so concentrated as to flow with difficulty, and to present an almost tarry consistence. As there is an effort to repair the loss of water by absorption, the organs and tissues become shrunken and dry, the secretions are diminished or checked, the circulation is slow, the blood-pressure reduced, the pulse becomes feeble or imperceptible. The appearance of potash-salts in the plasma, indicates that red blood-corpuscles are destroyed. If reaction ensue after the choleraic discharges cease, the blood is rapidly restored to its normal percentage of water by the absorption of fluids taken into the system.

Hyperinosis—Hypinosis.

An abnormal increase in the amount of fibrin in the blood constitutes *hyperinosis;* an abnormal diminution of the fibrin is called *hypinosis*. In former times, when venesection was more frequently practised, physicians paid much attention to the amount of fibrin in the blood, to the rapidity with which it coagulates, and to the appearance of the coagulum. It is now recognized that many fallacies existed in the former methods of analysis, and that estimations of the fibrin do not have the diagnostic value formerly attributed to them. From the investigations of Denis, Schmidt, Hammarsten, Mantegazza, it appears that, while fibrin is formed from a substance called fibrinogen which is dissolved in the blood-plasma and in most transudations and exudations, solutions containing fibrinogen alone do not yield fibrin, but that the presence of one other substance called fibrin-ferment, and perhaps of several other substances, is required for the transformation of fibrinogen into fibrin. This fibrin-ferment is furnished by the white corpuscles and perhaps by the hæmatoblasts of Hayem. The action of this substance seems to be fermentative or catalytic, it entering into no chemical union with the fibrinogen.

It is now thought that the statements formerly made as to the increase or diminution of the fibrin in the blood, which led to the recognition of the con-

ditions called hyperinosis and hypinosis, have little value in the light of recent discoveries. The quantity of fibrin which coagulates from the blood is believed to depend less upon the amount of fibrin-forming substance in the blood, than upon the presence or absence of conditions which favor or impede the coagulation. Thus, in acute infectious diseases, acute icterus, and other diseases in which hypinosis was supposed to exist, the imperfect coagulation of the fibrin is now attributed to decomposition of the blood and to the presence of agencies which interfere with coagulation. Hoppe-Seyler,[1] however, still maintains the accuracy and value of quantitative estimations of the fibrin. Human blood yields in health 0.1 to 0.4 per cent. of dried fibrin. In hydræmia and in acute inflammatory diseases, more fibrin is formed from a given quantity of blood than in health. This excess in hydræmia doubtless depends upon the greater amount of plasma. In acute rheumatism and in erysipelas more than one per cent. of fibrin has been obtained from the blood, and in pneumonia over 0.5 per cent.

The so-called *buffy coat*, or *crusta inflammatoria*, is due to the slow coagulation of the fibrin, so that the red corpuscles have time to sink and leave the upper layers of the coagulum uncolored. This appearance in blood removed by venesection is not characteristic of inflammation, and has no diagnostic value.

Leucocytosis.

According to the nomenclature proposed by Virchow, a temporary increase in the number of white corpuscles in the blood is called *leucocytosis;* a permanent and usually much greater increase constitutes the disease called *leucocythæmia* or *leukæmia*. The number of white corpuscles in the blood is subject to much greater variation, within normal limits, than is that of the red corpuscles. The proportion is usually estimated as 1 white to 350–500 red. Leucocytosis, indicated by a moderate increase in the number of white corpuscles, has been observed, as a physiological condition, during digestion and in pregnancy. According to Patrigeon,[2] digestion is attended only exceptionally with increase of white corpuscles. Leucocytosis is present in inflammations attended with profuse suppuration. It is also observed in fevers. A relative and sometimes an absolute leucocytosis is often present in anæmic conditions, as already mentioned. The increase in white corpuscles in these conditions rarely approaches in degree to that found in the disease leucocythæmia, in which the proportion of white to red may be as 1 to 10, 1 to 3, and even in one case 3 white were present to 2 red. In leucocythæmia the number of red corpuscles is greatly diminished, and the symptoms are in chief part those of anæmia. This disease will be considered in the second part of this work, in the section treating of diseases of the hæmato-poietic system.

Alterations in the Gases of the Blood.

The gases contained in the blood are oxygen, carbonic acid, and nitrogen. The oxygen is, for the most part, in unstable combination with hæmoglobin, in the form of oxyhæmoglobin. There may be also a small amount of oxygen simply dissolved or absorbed in the plasma. The oxygen may be easily driven out of the blood by certain other gases, as carbonic oxide or by a vacuum. Carbonic acid gas exists in the plasma and in the red corpuscles of the blood only in combination with alkalies or alkaline salts; none is held in

[1] Hoppe-Seyler, Physiologische Chemie, p. 419, Berlin, 1879.

[2] Patrigeon states the normal proportion between white and red to be 1 to 1200–1500. Recherches sur le nombres des globules rouges et blancs du sang. Thèse, Paris, 1877.

simple solution (P. Bert). Nitrogen is simply absorbed. Of course, the stable combinations of these gases in the blood do not here enter into consideration. Probably the only influence which can *increase* the quantity of oxygen in the blood sufficiently to give rise to morbid symptoms, is the *inhalation of compressed air*, and here the evil effects are due, less to the increased quantity, than to the increased tension, of the oxygen in the blood.[1] Death in compressed air may result as well from excess of carbonic acid in the blood, as from excess of oxygen. The effects of changes in the barometric pressure have been ably studied by Paul Bert,[2] who investigated the influence of compressed and of rarefied air upon men and animals. He found that evil effects are felt under a pressure of 6 atmospheres; that in animals convulsions appear when the pressure reaches 20 atmospheres, and that death rapidly ensues when the pressure equals 25 atmospheres. As the hæmoglobin in normal arterial blood is nearly or quite saturated with oxygen (Herter), it is mainly the dissolved oxygen of the plasma which is augmented by inhaling compressed air. According to Bert, death ensues when the proportion of oxygen in the arterial blood is augmented one-third. Under the influence of this super-oxygenation of the blood, the oxidation of the tissues is diminished, the production of carbonic acid, the excretion of urea, and the destruction of sugar in the blood are lessened, and, as a result, the temperature is lowered.

The study of the effects of high atmospheric pressure upon man has acquired especial interest in consequence of the extensive use made of compressed air in engineering operations. In diving-bells, in mines in which compressed air is used to keep water from flowing into the shafts, in the caissons employed in the sinking of piers, men are subjected to the influence of compressed air, but the degree of compression rarely suffices in itself to produce grave symptoms. Some inconvenience may be felt from pain in the ears, and sometimes in the frontal and maxillary sinuses. There is, however, danger in passing rapidly from highly compressed air into the normal atmosphere, if the stay in the former have been long. A number of fatal accidents have occurred from ignorance or negligence in this respect. Hoppe-Seyler, and subsequently Bert, found that if the pressure have been considerable, and it be too rapidly removed, nitrogen is set free in the blood in the form of gaseous bubbles which, collecting in the right side of the heart, stop the circulation and cause sudden death. Nitrogen is absorbed by the blood in accordance with Dalton's law for the absorption of gases by fluids, and consequently accumulates in the blood in considerable quantity in compressed air. There have been observed occasionally to follow the removal of the pressure certain symptoms, to which A. H. Smith[3] has given the name of the *caisson-disease*, and the explanation of which is not established. The most frequent and important of these symptoms are, pain in one or more of the extremities, and sometimes in the trunk, epigastric pain and vomiting, paralysis more or less complete, general or local, most frequently confined to the lower half of the body, headache, and vertigo. According to Smith, the duration of the caisson-disease varies from three or four hours to six or eight days. The paralysis may disappear within twelve hours, or may continue for weeks. Death occurs only in cases which are severe from the first. Smith refers the symptoms, at least in severe cases, to congestion of the brain and spinal cord. It is, however, not improbable that at least some of the symptoms may be due to the liberation of bubbles of nitrogen in moderate amount, or in situations not

[1] In a recent article, G. v. Liebig (Münchener ärztl. Intelligenzbl., No. 19, 1879) explains the injurious influence of compressed air by the mechanical hindrance which it offers to expiration.

[2] Paul Bert, La Pression barométrique, etc., Paris, 1878.

[3] A. H. Smith, The Effects of High Atmospheric Pressure, Brooklyn, 1873.

immediately endangering life. Morphine, atropine, and especially ergot, were found useful in relieving the pain. The main reliance, when the symptoms are urgent, and especially when life is endangered soon after removal of the pressure, is return to compressed air. Bert has proposed the inhalation of oxygen to displace the free nitrogen from the blood by diffusion.

Air compressed not more than from one to five atmospheres has been employed as a therapeutical agent, chiefly in certain pulmonary disorders. The influence of moderately compressed air is to diminish the number of pulsations of the heart, and to increase the capacity of the lungs by compression of the intestinal gases. According to Bert, the maximum of oxidation takes place under a pressure of three atmospheres.

A condition attributed to excess of oxygen in the blood is a temporary cessation of the respiratory acts, which is observed to follow violent and full inspirations, and which has been studied chiefly by physiologists on animals, the condition being induced by vigorous artificial respiration. To the cessation of breathing as thus produced, the term apnœa is limited by some German writers; but this term, as usually applied, embraces the various conditions which occasion dyspnœa. In the latter comprehensive sense, inclusive of serious disturbances of hæmatosis, whether accompanied or not by a sense of the want of breath or dyspnœa, the term will be used in this work. According to Hoppe-Seyler,[1] apnœa, in the limited sense above mentioned, is to be attributed, not to an excess of oxygen in the blood, but to fatigue of the respiratory muscles.

Deficiency of oxygen in the blood is of much greater pathological importance than its increase. If the quantity of oxygen in the blood be greatly diminished, there follows a group of symptoms to which the names *suffocation*, *asphyxia*, *cyanosis* are applied. Causes which reduce the amount of oxygen in the blood sufficiently to produce suffocative symptoms are, 1, diminution in the supply of oxygen to the pulmonary capillaries, as from breathing in rarefied air and in small closed spaces, also from obstruction or compression of the air-passages as in croup; from diseases which lessen the respiratory surface of the lungs or interfere with their function, as pneumonia, phthisis, pneumothorax, asthma, œdema; from interference with the respiratory centre, as in certain affections of the central nervous system, and in narcotic poisoning; 2, obstruction to the circulation in the lungs, as from embolism of the pulmonary artery and in valvular lesions of the heart; 3, diminution in the amount of hæmoglobin in the blood such as results from profuse hemorrhages; 4, displacement of oxygen from its combination with hæmoglobin by other gases which enter into a firmer combination, as carbonic oxide from which many intentional and accidental cases of poisoning have resulted (nitric oxide also displaces the oxygen, but being irrespirable need not here be considered); 5, rapid reduction of oxyhæmoglobin by gases which seize the oxygen, such as sulphuretted hydrogen, and, probably, also phosphuretted, arseniuretted, and antimoniuretted hydrogen, which further decompose the blood. Mention here should also be made of the asphyxia of new-born children, asphyxia neonatorum, which is due to separation of the placenta or to closure of the umbilical vessels before birth. After death from rapidly produced suffocation, the blood is of a dark color, and usually, although not always, fluid or imperfectly coagulated, the right cavities of the heart are, as a rule, distended with blood, the mucous membrane of the larynx and trachea congested, ecchymoses are frequently present beneath the pleura and pericardium. In consequence of the fluid condition of the blood, there is hypostatic congestion of most organs, and livid spots (livores mortis) on the most dependent

[1] Hoppe-Seyler, Zeitschrift für physiologische Chemie, iii. p. 105, 1879.

parts of the surface of the body. Chemical analysis of the blood, just before death, shows the oxygen to be nearly or entirely absent, and the carbonic acid to be more or less increased in amount. After poisoning by carbonic oxide the blood is bright red instead of dark, unless this gas has been partly or wholly converted into carbonic acid. The symptoms of suffocation are, at first, dyspnœa, as indicated by increase in the rapidity or in the depth of the respiratory movements, or in both; convulsions, which are usually absent when the suffocation is not rapidly induced, and which, even in rapid suffocation, may fail, as in drowning; lowering of the temperature; elevation of the blood pressure; at first slowing of the pulse from irritation of the vagi, then increased rapidity from paralysis; dilatation of the pupils; protrusion of the eyeballs (exophthalmus), and a dark blue, so-called cyanotic hue of the surface of the body. At a late stage these symptoms may become considerably modified. This is the asphyctic stage proper. In it the color becomes less dark, the dyspnœa is lessened or disappears, the pulse is small and frequent, reflex excitability is lessened, and finally unconsciousness, anæsthesia, and death follow. Sugar may appear in the urine in cases of suffocation. The symptoms which have been enumerated are modified in individual cases, especially by the rapidity with which the oxygen in the blood is lessened in amount. Dyspnœa, with more or less marked suffocative symptoms, is an important element in many diseases which will be considered in Part II. of this work. There has been much dispute as to whether the symptoms of suffocation, particularly dyspnœa, are due to the loss of oxygen in the blood or to the excess of carbonic acid. It is now quite certain that in rapid suffocation the dyspnœa is due chiefly to the diminished quantity of oxygen. It is possible to produce all of the symptoms of asphyxia in animals by lessening the amount of oxygen without increasing the amount of carbonic acid in the blood (Pflüger), and although a large accumulation of carbonic acid in the blood also causes dyspnœa, the amount of this gas found in the blood in most cases of asphyxia is not sufficient to explain the symptoms. The treatment consists in removal of the cause, if possible, and in efforts to increase the quantity of oxygen in the blood. This increase is best effected by the employment of artificial respiration and by the inhalation of oxygen. In poisoning by carbonic oxide the transfusion of blood has proved successful. Special therapeutical indications will be considered in the second part of this work.

Although, as has been mentioned, in most cases of suffocation there is an excessive amount of carbonic acid in the blood, this excess does not usually suffice to produce dyspnœa. It is, however, possible to produce this symptom by inhaling air containing a large quantity of carbonic acid, even if there be no diminution of oxygen. The asphyxia is developed more slowly than when resulting from lack of oxygen. The experiments of Raoult[1] have shown that the presence of carbonic acid in the inspired air diminishes the quantity of carbonic acid produced in the body, and especially the amount of the oxygen consumed. The experiments of Friedländer and Herter[2] upon animals demonstrate that, if the quantity of oxygen be normal, inhalation of air containing less than 20 per cent. of carbonic acid produces symptoms of irritation, as increased frequency of respiration and increased blood-pressure, but no really poisonous effects; but if the amount of carbonic acid be increased to about 30 per cent., symptoms of depression follow, the breathing becomes slower and weaker, the blood-pressure sinks, voluntary and reflex movements are weakened and finally abolished, the temperature falls, and the animal dies in the course of a few hours. If the quantity of carbonic acid be increased to the maximum, the

[1] Raoult, Comptes rendus, t. 82, p. 1101.
[2] Friedländer and Herter, Zeitschr. f. physiol. Chemie, Bd. ii. s. 99, 1878.

symptoms of depression follow very rapidly, and death occurs frequently within half an hour. According to Bert, symptoms of carbonic acid poisoning do not appear until all of the alkali in the blood has been saturated with carbonic acid and the gas begins to be dissolved in the plasma.

Increase and diminution in the oxygen and increase in the carbonic acid are the only alterations in the gases of the blood which require to be considered under the general pathology of the blood.

Changes in the Albumen, Fat, and Inorganic Salts of the Blood.

These changes can be dismissed with a few words. Enough has already been said in connection with hydræmia and anhydræmia concerning alterations in the quantity of albumen. Fat is probably always present in the blood-plasma in health. Its average amount is estimated at two to three parts per thousand, but the quantity varies considerably within normal limits. The amount of fat in the blood is increased during the digestion of fatty substances, when the blood may acquire a milky or chylous appearance from the molecules of fat. In diabetes the blood often has a slightly milky appearance from an increased amount of fat. This condition of the blood has been called *lipæmia*. It is said that in diseases of the liver and in chronic alcoholismus there is increased amount of fat in the blood. This chylous condition of the blood is, of course, not to be confounded with the entrance of oil-drops into the blood after fractures and certain other morbid states. This fatty embolism has already been described (see Embolism and thrombosis). We are not able to assign any pathological importance to a chylous condition of the blood.[1]

Although the inorganic salts are present only in small amount in the blood (8 parts to 1000, of which about one-half is chloride of sodium) they undoubtedly have an important part in the vital processes. The effects of their withdrawal from the food are described in works on physiology, and can hardly claim pathological importance. Some writers have attributed the symptoms of scorbutus to a deficiency of alkaline carbonates, or to a lack of potash-salts in the blood, but we possess no very satisfactory chemical analysis of the blood of scorbutic individuals. There seems to be no diminution in the chlorides of the blood in pneumonia and in the fevers, notwithstanding sometimes an entire absence of chlorides in the urine in these affections. The diseases rachitis and osteomalacia are supposed by many to depend upon an insufficient amount of the salts of lime in the blood. According to C. Schmidt there is a definite relation between the quantity of albumen and that of salts in the blood, diminution in the albumen being attended by increase in the salts.

[1] Sanders and Hamilton (Edin. Med. Journal, vol. ii. p. 47, 1879), however, consider lipæmia and the resulting fatty emboli as the cause of the dyspnœa and other symptoms of diabetic coma.

CHAPTER VII.

GENERAL PATHOLOGY OF THE BLOOD—(Concluded.)

Glycohæmia—Acetonæmia—Uræmia—Ammoniæmia—Uricæmia or Lithæmia—Cholæmia—Cholesterænia—Melanæmia—Septicæmia—Pyæmia.

Glycohæmia.

GLYCOHÆMIA signifies the presence of sugar in the blood. A small amount of grape-sugar exists normally in the plasma of the blood. This normal amount is estimated at from 1 to $2\frac{1}{3}$ parts per 1000. The quantity of sugar is about the same in venous and in arterial blood, and does not seem to be essentially influenced by the diet, beyond the fact that sugar is absorbed from the intestine by the portal vein.

If the quantity of sugar in the blood exceed a certain amount ($2\frac{1}{4}$–3 parts per 1000 according to Bernard), sugar appears in the urine, constituting the condition called *glycosuria*. Many physiologists indeed maintain that a trace of sugar is present in the normal urine, the quantity being so small as to be unrecognizable by the ordinary tests. Milk-sugar is present in the urine of females during lactation. This condition is *lactosuria*. Glycosuria may be a temporary condition in health and in disease, or it may be long-continued. Prolonged glycosuria is attended by a group of characteristic symptoms, and is called *diabetes mellitus*,[1] a disease which will be considered in Part II. of this work. Certain considerations pertaining to the pathogeny of glycohæmia as a morbid state, find their place appropriately under the general pathology of the blood. The amount of sugar in the blood of diabetic individuals may be 9 parts to 1000 of serum (Hoppe-Seyler). There has been found in diabetes increased decomposition of the nitrogenous constituents of the body, as indicated by an excess in the excretion of urea out of proportion even to the large amount of ingesta. There is diminution in the absorption of oxygen and in the excretion of carbonic acid. Quincke found an increased amount of iron in various organs of the body, indicating, he supposes, increased destruction of red blood-corpuscles. In the milder cases of diabetes the sugar may be made to disappear from the urine by withholding saccharine and amylaceous articles of food; in other cases the sugar remains, although in diminished amount, during a diet of strictly animal food. Von Mering found sugar still in the urine of a diabetic patient after abstinence from food for twenty-six hours. Permanent glycosuria may appear as a symptom of certain affections of the central nervous system, particularly tumors and hemorrhages involving the medulla oblongata. With this occasional exception, there are found in diabetes mellitus no pathological changes to which the increase of sugar in the blood can be referred with any certainty.

There are numerous theories as to the nature of diabetes mellitus, but none has yet obtained general acceptation. Most of these theories are little more than conjectures based chiefly on physiological experiments, the results of

[1] Diabetes insipidus or polyuria without sugar in the urine is not considered in this connection.

many of which are still in controversy, or, with our present knowledge, neither admit of interpretation nor shed much light upon diabetes as it occurs in man. A temporary glycosuria can be produced in animals in a great variety of ways, of which the longest known and most celebrated is puncture of the floor of the fourth ventricle, the *piqûre* of Bernard. This is thought to cause vaso-motor paralysis of the bloodvessels of the liver and to hasten thereby the circulation through the organ. Among other methods of producing experimentally glycosuria, may be mentioned injuries of various parts of the brain and of the spinal cord, destruction of sympathetic ganglia or division of sympathetic nerves in different situations, irritation of the depressor-nerve, poisoning with curare, carbonic oxide and most narcotics, injection of large quantities of solutions of common salt into the blood, and in cats simple fixation and tracheotomy.

There are two possibilities as to the accumulation of sugar in the blood. One is that there is increased access of sugar to the blood, the other that there is diminished consumption of sugar in the system. An increased amount of sugar has been supposed to come from different sources; from the liver, from the intestine, from the muscles, or from the tissues in general. The theory of the *hepatogenous origin* of diabetes mellitus is the one which has been most widely accepted since the researches of Bernard upon the glycogenic function of the liver. There are two modifications of the theory that in diabetes an increased quantity of sugar passes from the liver into the blood. In order to understand these two forms of the hepatogenous theory, it is necessary to know that not only is it thought that glycogen is formed out of sugar, but that it is also converted into sugar. According to one view, in diabetes the production of sugar in the liver is abnormally great. This may be due to increased formation of glycogen or of sugar-ferment, or it may be the result of too rapid passage of glycogen from the hepatic cells into the blood where it is converted into sugar. Pavy supposes that the liver produces sugar in diabetes, but not in health. Another form of the hepatogenous theory is that the sugar which is brought to the liver by the portal vein, whether in normal or in abnormal quantity, is not converted into glycogen, but passes unchanged through the liver into the hepatic vein. According to the former view, there is an increase of the sugar-forming function of the liver; according to the latter, its glycogen-forming function is interfered with. Many of the advocates of each view hold that the primary change is increased rapidity of the portal circulation in the liver. This assumption is based upon experiments intended to show that temporary glycosuria is produced in animals by paralytic distension of the bloodvessels of the liver. The theory that diabetes depends upon an increased production of sugar in the liver, is founded on the doctrine that the formation of sugar from glycogen is a normal function of the liver. This theory has been opposed by investigations which have resulted in a denial of the existence of a sugar-forming function in the liver.[1]

In favor of the theory that diabetes mellitus is due to the non-conversion of sugar into glycogen in the liver, the following experiments have been adduced: If sugar be injected into the jugular or the crural vein of an animal, it soon appears in the urine, whereas, a larger amount may be injected into the mesenteric vein without causing glycosuria. Cases are reported in which the ingestion of sugar or of amylaceous substances has induced glycosuria in cirrhosis of the liver, a disease in which a considerable part of the hepatic parenchyma is destroyed, and the portal circulation obstructed. Bernard produced glycosuria by feeding with sugar and amylaceous substances

[1] Abeles (Œstr. med. Jahrb., 1875, p. 269), v. Mering (Arch. f. Anat. u. Phys., 1877, p. 379), Bleile (Ibid., 1879, p. 59).

animals in which the portal vein was closed. On the other hand, it has been shown that puncture of the fourth ventricle does not cause glycosuria if the animal has been poisoned with arsenic or phosphorus, substances which induce fatty metamorphosis of the liver.

The theory of Huppert is perhaps the best presentation of the view that diabetes mellitus depends upon diminished oxidation of the sugar. The researches of Pettenkofer and Voit regarding the nutritive changes in a diabetic patient, led them to advocate this theory. According to these investigators, diabetes mellitus is due to a general disturbance of nutrition, in consequence of which the albuminous constituents of the body (the organic albumen) undergo abnormally rapid metamorphosis. Proof of this they find in the amount of urea excreted, which exceeds that produced from the ingesta. Hence diabetic individuals rapidly emaciate. Sugar, like urea, they consider to be a normal product of the decomposition of albuminous substances. In health this sugar is rapidly oxidized. In diabetes less oxygen is absorbed than normal, notwithstanding the increased amount of oxidizable substances in the blood. This diminution in the absorption of oxygen is attributed to destruction of red blood-corpuscles, or to their abnormal constitution in consequence of their participation in the general mal-nutrition of the body. Inasmuch as the sugar produced in increased amount by metamorphosis of albumen, does not find the proper quantity of oxygen for its combustion, it accumulates in the blood and causes abnormal glycohæmia. The observations of Quincke[1] are not in harmony with Pettenkofer and Voit's explanation of the diminished absorption of oxygen. Quincke found not only no reduction in the amount of hæmoglobin in the blood in diabetes, but in one case even an actual increase. The diminished oxidation of the sugar in diabetes has been attributed also to a reduction of the alkalinity of the blood.

Dickinson,[2] believes that diabetes mellitus is always the result of changes in the central nervous system. The most important of these changes he considers to be dilatation of the arteries and of the perivascular spaces and minute hemorrhages with disintegration of nerve-elements. Changes similar to those described by Dickinson, however, have been found in other diseases, and are not constant in diabetes. While it is true, as has been mentioned, that, in certain cases of diabetes mellitus, marked changes have been found in the brain, especially in the pons and medulla oblongata, there is not sufficient evidence for believing that all cases of diabetes are of nervous origin.

It can serve no useful purpose to describe other theories which have been proposed, or to attempt to criticize further those which have been cited. They all rest upon too uncertain a foundation. Until we have more positive knowledge as to the source of sugar in the healthy organism, and as to its metamorphoses, we cannot hope for any satisfactory explanation of the abnormal accumulation of sugar in the blood and in the urine in diabetes mellitus.

The transient appearance of a small quantity of sugar in the urine in various diseases, has no more pathological importance than the occasional appearance of a trace of albumen.

Acetonæmia.

The presence of a substance called *acetone* in the blood in certain diseases has been supposed to be the cause of grave symptoms. This substance, which is a derivative of acetic acid, is recognized in the breath and in the urine by a peculiar odor resembling that of chloroform. Its presence has been demon-

[1] Quincke, Virchow's Archiv, Bd. 54, p. 542.
[2] Dickinson, Med. Times and Gaz., March 9, 1870 ; and Treatise on Diabetes, 1875.

strated by chemical analysis in the urine of diabetic patients who emitted the characteristic odor. This odor has led to the suspicion of the presence of acetone also in certain cases of gastritis, cancer of the stomach, fevers and alcoholic intoxication. Acetonæmia has been adduced as the cause of a form of coma which occurs in diabetes, usually accompanied by severe dyspnœa, and often preceded by a period of excitement. The odor of acetone has been detected in the breath and the urine in certain cases of diabetic coma, but not in all. Kussmaul found that large doses of acetone produced in animals a kind of intoxication, but he does not consider that his experiments prove that diabetic coma is the result of acetonæmia. He has administered without injurious effects a drachm to a drachm and a half of acetone daily for weeks at a time in cases of phthisis.

Uræmia.

By *uræmia* is understood the accumulation in the blood of excrementitious substances of the urine. The term is usually applied to a group of symptoms which appear when the function of the kidneys is interrupted or much impaired. The most important of the uræmic symptoms are coma and epileptiform convulsions, preceded often by headache, vomiting, and diarrhœa. The convulsions usually precede the coma, but either may appear alone. Amaurosis, dyspnœa, and maniacal delirium are also to be included among the occasional manifestations of uræmia. In the majority of cases, uræmia is the result of some form of acute or chronic diffuse inflammation of the kidneys (Bright's disease). It may attend any disease in which the excretion of urine is more or less completely suspended, as double hydronephrosis, stricture of the urethra, cystitis, etc. In uræmia, as a rule, the quantity of urine, and especially the quantity of urea excreted, are diminished, the urine is albuminous and contains casts, and dropsy is present, or it has preceded the attack. There are, however, exceptions, especially as regards the quantity of urine and the presence of dropsy. We cannot account for the fact that in one case uræmia appears, and in another it fails, although the conditions are apparently the same in both. Notwithstanding much research, no thoroughly satisfactory explanation of the uræmic phenomena has yet been reached.

The oldest and still most prevalent theory is, that uræmia is due to the accumulation of urea in the blood. The arguments which have been adduced in support of this view are, that urea, introduced into the blood of animals, produces symptoms similar to those of uræmia in man, and that in uræmia urea is in excess in the blood. The majority of experimenters agree that the injection even of large quantities of urea into the blood of healthy animals is harmless.[1] Urea may be fed freely to dogs without injurious effects if the animals be allowed to drink water. Inasmuch as urea is rapidly eliminated by healthy kidneys, these experiments do not prove that urea is innocuous when its excretion from the body is checked. In order to determine the effects of urea under conditions in which it cannot so readily be eliminated, it has been injected into the blood of animals whose kidneys have been removed. Uræmic symptoms develop in nephrotomized animals which survive the operation, in every case sooner or later. That the appearance of these symptoms is hastened by the injection of

[1] Feltz and Ritter found that when urea in large doses produced convulsions it was always contaminated with ammonium-salts. It never produced convulsions when pure. Compt. rendus, T. 86, No. 15, 1878.

Picard recently finds, in opposition to most observers, that the rapid injection of concentrated solutions of urea into the jugular vein of dogs produces uræmic symptoms with fatal termination. He does not attribute the symptoms to the direct action of the urea, but to suspension of the renal excretion. Gaz. med. de Paris, 1879, No. 5.

urea, has not been established. Voit found that symptoms resembling those of uræmia are produced if the rapid elimination of urea fed to dogs be prevented by withholding water. The same effects were observed after feeding in the same way some other substances, such as benzoate of soda. Voit therefore does not attribute specific poisonous properties to urea, but thinks that uræmic symptoms appear when the accumulation in the blood of a variety of substances, including urea, uric acid, potash-salts, creatinin and extractive matters, becomes so great that the products of tissue-metamorphosis cannot be carried off. These waste products collect, not only in the blood, but in the tissues, and here check that interchange between the tissue-elements and the nutritive fluids, which is essential to the proper performance of cell-function. The results hitherto obtained by experimentation with urea, cannot serve as a basis of support for the doctrine that urea is the sole poisonous agent in uræmia.

The blood of uræmic individuals has been analyzed with the view of determining the injurious ingredients. The blood of animals, in which the kidneys have been extirpated or the ureters tied, has been found to contain urea in tenfold its normal amount, if the animals survive the operation two to four days. These experiments show that urea is not formed exclusively in the kidneys, but that it is produced elsewhere and conveyed to these organs by the blood. Normal blood contains 0.01 to 0.08 per cent. of urea. The quantity of urea has been found much increased in the blood of uræmic patients. Bartels mentions a case in which 0.8 per cent. of urea was found. Hoppe-Seyler found 0.127 per cent. These amounts are larger than has usually been found in uræmia. But other excrementitious substances as well as urea are present in excess. A notable increase of extractive matters (0.86 per cent., Hoppe-Seyler) has been found, the importance of which is not to be underestimated because they have hitherto defied chemical analysis. There is one factor which disturbs the certainty with which urea accumulates in the blood when the function of the kidneys is suspended, namely, the vicarious elimination of urea by other organs. Urea may be excreted vicariously by the stomach, intestine, and skin. It has also been found in larger percentage in dropsical effusions than in the blood. In the stomach and intestine urea is readily converted into carbonate of ammonia. Urea has repeatedly been observed in uræmia as a crystalline deposit upon the skin. The bile has been found to contain an abnormal amount of urea.

While urea has been found in excess in uræmic blood, there have been also cases of uræmia in which the amount of urea in the blood has been slightly, if at all, increased. In one case, Jacobsen[1] found the quantity of urea too small to admit of quantitative estimation. On the other hand, a large quantity of urea has been found in the blood without the coincidence of uræmic symptoms. Unless in these analyses there has been some error, it seems quite certain that there are cases of uræmia in which the symptoms are not due to the retention of urea in the blood.

A theory of uræmia elaborated by Frerichs with great skill, which obtained at one time considerable credence, is now generally discredited, at least, as regards its applicability to most cases This theory is, that uræmic symptoms are due to the presence, in the blood, of carbonate of ammonia produced by decomposition from the urea. There is no evidence for Frerichs's assumption that urea is decomposed into carbonate of ammonia in the blood. This decomposition, however, takes place in the stomach and intestine, carbonate of ammonia having been recognized often in the vomit of uræmic patients.

[1] Ziemssen's Cyclopædia of the Practice of Medicine, English translation, vol. xv. p. 130.

There is no doubt that carbonate of ammonia may be absorbed by the blood from the intestine, and that, in certain cases, which are rarer than was once supposed, it may be detected in the breath. It is true that the injection of carbonate of ammonia into the blood of animals produces more marked symptoms than does the introduction of urea. The most constant of these symptoms are convulsions, followed often by coma, with infrequency of the pulse and respiration. But while carbonate of ammonia always produces one and the same group of symptoms, mainly those of irritation, on the other hand the manifestations of uræmia are various, and only in a certain proportion of cases are they analogous to those produced by the ammonia-salt. Carbonate of ammonia has been detected in small quantity in the blood in uræmia, but it has also been found absent in many cases.

Traube referred the uræmic phenomena to cerebral œdema and consequent cerebral anæmia. The œdema he attributed to hydræmia and high arterial pressure, conditions which are often, but not invariably, present in uræmia. Œdema and anæmia of the brain are found when no uræmic symptoms were manifested during life, and they are by no means constantly present after death from uræmia. Œdema of the brain may often be regarded with more propriety as the result, rather than as the cause, of convulsions.

It is held by some writers that uræmia is not always produced in the same way, but that, in different cases, the causes are different. Bartels was an eminent advocate of this eclectic view. Jaccoud attempts even to diagnosticate between uræmia due to toxæmia and that due to œdema of the brain. But no essential differences have been detected, as regards symptoms, between cases of uræmia in which the blood was loaded with urea, and those in which no excess could be determined; between those in which carbonate of ammonia was found in the blood, and those in which it was absent, or between cases accompanied with hydræmia, and those without the latter pathological condition.

It is only established with regard to the cause of uræmia, that this condition is the result of an abatement of the function of the kidneys, and that this abatement is followed by an accumulation of excrementitious substances in the body. It is inconceivable that the accumulation in the blood and tissues of waste products should not have an injurious effect. Perhaps the following explanation of the uræmic phenomena is most in harmony with clinical and experimental observations: The uræmic symptoms are the result of the retention in the system of excrementitious materials. It is the entire mass of waste products, and not any single element, which is the source of trouble. The nature of these waste materials is very imperfectly known. They probably consist mostly of nitrogenous substances in different stages of the metamorphosis of which urea is the final stage. The non-elimination of the excretory products, causes an incomplete metamorphosis of the waste nitrogenous elements. These are retained, not only in the blood, but, finally, in the tissues. The nutritive processes are thereby disturbed. As the uræmic symptoms are chiefly of nervous origin, it is necessary to emphasize especially the disturbance of nutrition in the nervous system.

Ammoniæmia.

The occasional absorption of carbonate of ammonia produced from urea excreted by the intestine, has been mentioned already. Whether the amount of carbonate of ammonia, which thus gains access to the blood, ever suffices to produce poisonous symptoms, is uncertain. There is, at least, not sufficient ground for believing that uræmia is, in reality, ammoniæmia. An ammoniacal state of the blood has also been referred to the absorption of carbonate of

ammonia formed in decomposed urine, in cases of retention of urine and of cystitis, from stricture of the urethra, enlarged prostate, paralysis of the bladder, pyelitis, etc. Musculus succeeded in isolating from the urine, in a case of cystitis, a ferment capable, in a short time, of transforming urea into carbonate of ammonia. Pasteur and Joubert found this ferment only when bacteria are present, and believe that it is produced by these organisms. This ferment gains access to the urine from without, chiefly by catheterization. Some writers have considered ammoniæmia the cause of the symptoms often observed in the late stages of cystitis and of pyelitis. These symptoms are, irregular chills, fever, dryness of the mucous membranes exposed to the air, vomiting, diarrhœa, delirium, somnolence, and coma. Ammoniacal exhalations from the lungs and the skin are sometimes evident. As suggested by Rosenstein,[1] these symptoms are rather those of septic infection than of ammoniæmia. They do not at all resemble the symptoms induced in animals by the injection of carbonate of ammonia. Convulsions are among the most constant and prominent effects of poisoning with carbonate of ammonia, but they are absent in this so-called ammoniæmia.

Uricæmia—Lithæmia.

Uric acid exists in minute quantity in the blood in health. Its abnormal accumulation constitutes the condition to which, in the first edition of this work (1866), was applied the name uricæmia. Subsequently the name lithæmia was applied to it by Murchison. Garrod has shown that an abnormally large quantity of uric acid is present in the blood in gout.[2] It may also exist in increased amount in chronic lead-poisoning, leucocythæmia, and some other conditions. The exact form in which uric acid exists in the blood is not known, but it is probably as the neutral urate of soda. The acid urate of soda is much less soluble than the neutral salt. The accumulation of uric acid in the blood is a constant attendant of gout, and is regarded by Garrod as the cause of most of the gouty symptoms. The most characteristic of these symptoms is the deposition, in various situations, of concretions of urates, accompanied often by inflammatory processes. The gouty concretions, or tophi, as they are called, consist of urate of soda, probably as an acid salt, combined often with urate of magnesia and of lime, and carbonate and phosphate of lime. These deposits are found in and about the joints, especially the small joints of the foot and hand, in the cartilage of the pinna of the ear, in the straight tubes of the kidney, in tendon, in the skin, nerves, vessel-walls, in the membranes of the cord, and in the spongy substance of bone. The concretions consist partly of acicular crystals and partly of granules. True gouty inflammation is always accompanied with a deposition of urate of soda in the inflamed part. The kidneys are often diseased in the late stages of gout, being small and granular, with increase of connective tissue, deposits of urates in the pyramids, and frequently waxy degeneration of the glomeruli and vessels. The urinary secretion in gout was found by Garrod to be deficient in uric acid, especially just before a paroxysm. Stockvis found at the onset of a gouty paroxysm the excretion of urea and of the earthy phosphates diminished. Others have found the excretion of phosphoric acid during the attack augmented. In the intervals between the paroxysms the excretion of uric acid may be either normal or diminished. The causes which have been assigned for an excess of uric acid in the blood, are the insufficient excretion of the acid, its increased formation in the system, and diminished

[1] Rosenstein, Ueber Ammoniæmia, Deutsche Zeitschr. f. pract. Med., No. 20, 1874.
[2] Garrod, On the Nature and Treatment of Gout and Rheumatic Gout, London, 1859.

alkalinity of the blood or lymph, whereby the neutral urates are converted into the less soluble acid urates. Upon the assumption that uric acid is converted in the system into urea by oxidation, the theory has been advanced that the uric acid diathesis is the result of incomplete oxidation of the nitrogenous products of metamorphosis. A deficiency of oxygen, however, has not been shown to exist in the uric acid diathesis. The most important elements in the etiology of the gouty diathesis are, heredity, the use of wines and malt liquors, and a diet rich in albuminous and fatty substances. Over-indulgence in these articles of diet is believed to cause an increase in the proportion of acids and of acid salts, and so to favor the precipitation of acid urates. Digestive disturbances, which are frequent in gout, may likewise be attended by the generation of organic acids, the absorption of which may reduce the alkalinity of the blood. It seems probable that the deposit of urate concretions depends not only upon increased formation and diminished excretion of uric acid, but also upon lessened solvent power of the blood and other fluids of the body.

Cholæmia.

The presence of the essential constituents of the bile in the blood constitutes the morbid condition called *cholæmia*. The constituents which come chiefly into consideration are the biliary coloring matters, bilirubin and biliverdin, and the salts of the biliary acids, namely, glycocholate and taurocholate of soda. If the coloring matter of the bile be present in the blood in sufficient amount, it appears, after a time (40 to 60 hours), in the urine and in the tissues, to which it gives a yellow color. This condition is called *icterus* or *jaundice*. The biliary coloring matter may appear in nearly all the tissues. The central and peripheral nervous system and cartilage, however, are very slightly, if at all, stained. All of the fluids, except the saliva,[1] tears, and mucus may be colored yellow. The biliary coloring matter may be easily recognized by Gmelin's test, with nitroso-nitric acid. The biliary coloring matters and the biliary salts are formed in the liver, and do not pre-exist in the blood. There is reason to believe that under pathological conditions, bilirubin may be formed in the blood from dissolved hæmoglobin. A number of substances, such as water, the biliary acids and salts, ether, chloroform, ammonia, and certain acids, when injected into the blood, cause the destruction of some of the red blood-corpuscles, and the appearance first of hæmoglobin, and afterwards of biliary coloring matter in the urine. Certain poisons and infectious principles are believed to act in the same way in human blood. Icterus, as thus induced by changes in the blood itself, is called *hæmatogenous*, in distinction from the usual form which is designated as *hepatogenous*. Hepatogenous cholæmia is dependent upon the absorption of the biliary coloring matter and of the biliary salts after their formation in the liver. The bile is probably absorbed, not directly by the bloodvessels, but by the lymphatics of the liver, and is conveyed by the thoracic duct to the blood. The causes of hepatogenous jaundice are: *first*, obstruction to the passage of bile, either in the small or large ducts; *second*, interference with the respiratory movements of the diaphragm, which aid in the propulsion of the bile; *third*, lowering of the blood-pressure in the portal vessels. As yet, no certain differential symptoms between hematogenous and hepatogenous icterus have been established. Some pathologists are even unwilling to admit the existence of hematogenous jaundice. The biliary salts have been found in small quantity in the urine in hepatogenous icterus, but it is not easy to detect them. Their absence can-

[1] According to Fenwick, bile may appear also in the saliva. The Lancet, Sept. 1, 1877.

not be considered, with our present knowledge, a sure sign of hematogenous icterus. These salts are known to undergo certain modifications in the blood, so that only a small quantity of those absorbed appears unchanged in the urine. In jaundice the biliary coloring matter exists, for the most part, dissolved in the fluids or diffusely infiltrated in the tissues, but it may present itself in the form of brown granules or of rhombic crystals of bilirubin, especially in the liver and in the kidneys. The influence of biliary salts in the blood has been experimentally studied upon animals. The injection of glycocholate of soda causes destruction of a certain number of red blood-corpuscles, diminution in the rapidity of the pulse, slowing of the respiration, sinking of the temperature, ecchymoses, and a weakness of the voluntary muscles. Apathy, and a certain degree of somnolence, are present even in the milder grades of icterus.

All clinical observers have met with exceptional cases of cholæmia in which the bile appears to have an intensely noxious influence on the nervous system, causing convulsions, coma, and death. The hæmic condition to which these effects are referable has been called "cholæmic intoxication." If uræmia be excluded, this condition denotes the presence in the blood of a constituent or of constituents of bile other than the bile pigment or the biliary salts, for the latter are present in cases of ordinary hepatogenous jaundice, in which no grave effects are manifested. Facts, physiological and pathological, point to the accumulation in the blood of cholesterin, as affording a rational interpretation of the phenomena of cholæmic intoxication, or, as it has been also called, grave jaundice. In 1862 A. Flint, Jr., demonstrated that the cholesterin in bile is a result of an excretory function of the liver, not previously recognized, and that it is an excrementitious principle derived chiefly from the disassimilation of nervous tissue. He also made examinations showing no increase of cholesterin in the blood in a case of ordinary hepatogenous jaundice, but a notable increase in a fatal case of jaundice with cirrhosis of the liver and ascites. To a morbid increase of cholesterin in the blood, he applied the name cholesteræmia.[1] Subsequent observations have tended to confirm the pathological conclusions based on these investigations. In 1873 Müller produced, by the injection of cholesterin into the blood of dogs, phenomena resembling those of the so-called grave jaundice.[2] In 1872 Picot ascertained the existence of cholesteræmia in a fatal case of grave jaundice.[3] It is believed by some that there are excrementitious substances other than cholesterin, which may be retained in the blood when the secretion of bile is arrested by extensive destruction of the hepatic parenchyma, or otherwise. The non-secretion of bile is called *acholia*. It is to be borne in mind that acholia does not necessarily involve cholæmia. The toxical effects of an accumulation of cholesterin, and of other excrementitious principles, may occur without, as well as with, jaundice. It is not improbable that a deficient elimination of cholesterin may occasion more or less of those indefinite ailments which are commonly embraced under the name *biliousness*, and which are relieved by remedies supposed to increase the functional activity of the liver. It should be added that, with regard to the pathological importance and relations of cholesteræmia, there is not as yet unanimity of opinions, and that experiments have been reported which contradict those of Müller.[4]

Melanæmia.

Melanæmia is that condition of the blood in which granular pigment is present. The pigment is black or brown in color, and in the form either of small roundish or angular granules, or of larger irregular flakes or masses. It exists partly free, and partly inclosed in leucocytes. The granules are sometimes surrounded by a little hyaline material, and they have been found occasionally in fusiform cells, such as exist normally in the spleen. Melanæmia is observed in cases of malaria. It is met with chiefly in the pernicious forms of intermittent and of remittent fever, and sometimes in chronic malarial cachexia. In the milder grades of intermittent fever, it is present, if at all, in very slight degree. The pigment in melanæmia is present not only in the blood but in certain organs, more especially the spleen, the liver, and the marrow of the bones. Pigment, however, may be found in any vascular part. The cortical substance of the brain acquires a dark, slate-like color from melanæmic pigmentation. In the spleen, liver, marrow of the bones, and lymphatic glands, the pigment is not only within, but frequently outside of, the bloodvessels. In the latter situation it may be either free or inclosed in cells. In the brain and other parts, the pigment is mostly intravascular. Small vessels may be occluded by pigment and pigment-cells. In melanæmia the number of red blood-corpuscles is diminished, either with or without an increase of the white corpuscles.

It is generally agreed that the pigment of melanæmia is formed out of the coloring matter of red blood-corpuscles. There are different views as to the situation in which the pigment is formed. Virchow and Frerichs maintain that it is formed in the spleen out of red corpuscles, which have either escaped from the bloodvessels, or are contained in venous thrombi; that it is conveyed by the portal vein to the liver, where it accumulates in considerable quantity and thence passes into the circulation. The spleen is enlarged, and more deeply pigmented than any other organ.

Opposed to the view that the pigment is produced in the spleen, is that advanced by Arnstein,[1] namely, that the formation takes place in the circulating blood, from red corpuscles destroyed by the malarial poison, and that subsequently there is an accumulation in those organs in which fine particles introduced artificially into the blood of animals are retained. If cinnabar or carmine, for instance, be injected into the blood, it accumulates in the spleen, marrow of the bones, and liver, and is thereby withdrawn gradually from the circulation. The accumulation of melanæmic pigment in precisely these organs, makes it probable that it is not formed in them, but is retained by them as in the case of foreign particles in general. According to Arnstein, the melanæmia gradually disappears after a malarial paroxysm, in consequence of the retention of the pigment in the organs named. He found pigment in other organs than the spleen, liver, marrow of bones, and certain lymphatic glands, only when death occurred, while pigment was present in the circulating blood. Melanæmia is developed during a malarial febrile paroxysm, and may disappear in the course of two or three days after the attack. It may also continue for months after the cessation of malarial paroxysms, as has been observed by Mosler. Melanæmia, in fact, seems to be an inconstant condition. It is certainly not infrequently absent when well-marked melanosis of the spleen and liver is found after death. The attempt to discover pigment in the blood in cases of severe malarial infection, is often unsuccessful. Although the views of Arnstein have been in the main confirmed by the studies of Kelsch who observed numerous cases of pernicious malarial fever in

[1] Arnstein, Virchow's Archiv, Bd. 61, p. 500.

Algiers, further investigations are required to determine the exact source of the melanæmic pigment.

The pathological effects of the melanæmic condition cannot be considered as established. Frerichs supposes that the accumulation of the pigment-granules and cells in different organs, may occasion obstruction to the circulation sufficient to interfere materially with the functions of the organs. It is uncertain whether the cerebral phenomena—stupor, delirium, convulsions, or paralysis—observed in certain forms of pernicious fever, are to be referred to the accumulation of pigment in the brain, or not. Ecchymoses and spots of softening in the brain have been thought to be the result of capillary emboli formed of pigmentary granules and cells. Similar changes have been observed in malaria without melanæmia.

Septicæmia and Pyæmia.

The diseases, pyæmia and septicæmia, will be considered briefly, as they belong to the domain of surgical, rather than of medical, pathology. The study of the nature of these diseases and of their mutual relations, involves extremely complicated and unsettled questions. Of the many distinctions which have been drawn between pyæmia and septicæmia, the one generally recognized, and, by some, alone accepted is that, in the former multiple abscesses are present, and in the latter they are absent. As to the infectious agents in the two affections, there is the widest divergence of opinion. Some hold that the morbific principle is the same in both, and that septicæmia and pyæmia are, therefore, identical diseases; but that in pyæmia venous thrombi are formed, from which infectious emboli are detached, causing abscesses, while these emboli are wanting in septicæmia. An old and still prevalent theory is that septicæmia, as the name implies, is due to putrid infection, and pyæmia to purulent infection. A further distinction maintained by some pathologists is, that the putrid material which causes septicæmia is a chemical substance soluble in the blood, while the infectious agent in pyæmia is molecular, consisting of specific bacteria. It is probable that, embraced under the name septicæmia, are a number of different processes, of which infection with decomposed material is only one variety; but our present knowledge does not enable us to prove this multiplicity in man, still less to define the different processes.

Septicæmia.—Most of the experiments and pathological investigations intended to elucidate the nature of septicæmia, are based on the assumption that septicæmia is due to infection with some poison contained in putrefying substances. It has been found that if animals be inoculated with fluid containing the products of decomposed albuminous substances, symptoms and pathological changes are induced analogous to those observed in certain forms of septicæmia in man. Since Pasteur rendered it probable that the ferment of decomposition either consists of, or is generated by, bacteria, much labor has been expended to determine whether the poisonous principle in experimental septicæmia is a chemical substance dissolved in decomposed fluids, or living germs. Panum[1] and other investigators have succeeded in isolating from decomposed fluids a substance soluble in water, and which, when injected even in minute quantity into the blood of animals, produces the symptoms of septicæmia. The name *sepsin* has been proposed for this substance. If decomposed fluid be entirely freed from bacteria by artificial means, it still retains noxious properties, although whether diminished in intensity, or not, is uncertain. While Panum admits that the poisonous material is produced by

[1] Panum, Virchow's Archiv, Bd. 60, p. 301, 1874.

the action of bacteria, he does not regard the bacteria themselves as the agents of infection. It is an interesting fact that the blood of septicæmic animals is much more virulent in its action than are putrid fluids. Septic blood, in fact, loses in virulence by decomposition. Davaine therefore distinguishes between septic material and putrid material. The septic blood of one animal may be innocuous when injected into an animal of a different species, while an almost infinitesimal quantity may suffice to infect an animal of the same species. Koch[1] has produced in animals forms of septicæmia invariably accompanied by characteristic bacteria in the blood. The septicæmia which he induced in mice was characterized by countless small rod-shaped bacteria, that of rabbits was accompanied by the presence of oval bacteria. The inoculation in rabbits of blood from septicæmic mice, did not produce the disease. It thus appears that the forms of septicæmia induced in animals are not, in all cases, the same. How far they are identical with septicæmic processes in man, is yet to be established. The results obtained by these experiments can not be used, at present, either for, or against, the doctrine that the agent of infection in septicæmia in man is a living contagion (Contagium vivum).

Septicæmia is observed most frequently after wounds, especially those complicated by injuries of bone, and by contusion or laceration of the soft parts. Its first symptoms appear usually in two to four days after the infliction of the wound, and before suppuration has been fairly established. The changes which render a wound a source of infection, are believed to be those of decomposition brought about by the agency of bacteria. The discharge from the wound is thin and ichorous, the surrounding parts are œdematous and sometimes gangrenous. Septicæmia may be caused also by gangrene, by ill-conditioned abscesses, and by inflammations in general. Usually, although not always, the focus of infection communicates with the open air. The hectic fever of phthisis, the suppurative fever of smallpox and certain other secondary fevers, are considered by some as due to septicæmia. There is some reason to believe that the healthy respiratory and intestinal mucous membranes can absorb septic poison generated outside of the body.

The changes found after death from septicæmia, are mostly of a negative character. Decomposition sets in rapidly. The blood is dark-colored, and coagulates imperfectly. Ecchymoses may be found in the serous membranes and in other parts. The spleen is often swollen and soft. Parenchymatous degeneration of the liver, heart, and kidneys is present. The solitary follicles and Peyer's patches may be swollen. Enteritis is less common in the septicæmia of man than in that induced in animals. Multiple abscesses are absent. There may be inflammation of the pleura or other serous membranes. Bacteria have been found in the blood of septicæmic patients during life. They are usually detected in the blood and organs after death. Most importance is attached to the presence of micrococci; but these, when found, have no characters distinguishing them from similar forms in several other infectious diseases, and in putrefying fluids. Good observers have failed to detect bacteria in septicæmic cases.

Septicæmia may be ushered in by a chill, but this is not constant, and repeated chills do not occur. There is, as a rule, a continuous, usually high, fever without distinct type. The skin is dry and hot, or, at times, there may be profuse perspiration. There is usually a yellowish hue of the skin, but the icterus is not intense. The pulse is small and frequent. The tongue and lips are dry. Diarrhœa is inconstant. The urine is scanty and high-colored. It may contain albumen. From the onset, the patient is indifferent and

[1] Koch, Untersuchungen über die Aetiologie der Wundinfections-krankheiten, Leipzig, 1878.

apathetic. There may be low delirium. Death is preceded by stupor, and, frequently, by decline of temperature. The duration may vary from a day or two to several weeks. It is usually about a week. It is supposed that septic poisoning in a mild or moderate degree not infrequently occurs, and ends in recovery; but in the cases in which the symptoms denote a grave affection, the proportion ending fatally is very large.

The principles involved in the prevention of septicæmia, embrace, especially, the treatment of wounds for which works on surgery must be consulted. The different modes of antiseptic dressing, and the open treatment of wounds are the means which have been most successful. After the symptoms have developed, large doses of quinine and of salicylic acid have been administered, on the ground that they possess antiseptic properties. Stimulants are required to support the strength of the patient.

Pyæmia.—Pyæmia, like septicæmia, is one of the traumatic, infectious diseases. As the name denotes, pyæmia originally was supposed to be due to the entrance of pus into the blood. The disease, however, is no longer attributed to the direct absorption, by the blood, of pus-corpuscles. The leucocytosis, frequently observed in pyæmia, indicates increase of white blood-corpuscles. There is no reason to suppose that pus-corpuscles, as such, are more harmful in the blood than white blood-corpuscles from which they probably originate. Many believe that there is inherent in pus a principle which excites inflammation, and, when absorbed by the blood, induces fever. If fresh pus from an acute abscess be injected beneath the skin of an animal, it causes suppuration; if it be injected into the blood, it excites fever and symptoms of blood-poisoning. Recent investigations, especially those of Kocher and of Ogston, have rendered it probable that acute suppurative processes are always accompanied by the presence of micrococci in the pus, and that these micrococci are different from the bacteria which cause putrefaction. Ogston[1] found the property of causing suppurative inflammation still possessed by these micrococci after they had been isolated by proper methods of cultivation from the other constituents of pus. The inoculation of pus free from micrococci (for instance, that from certain chronic abscesses), according to Ogston, does not cause suppuration. These micrococci both he and Kocher consider to be the agents of infection in pyæmia. Others hold the view that pyæmia is due to the absorption of decomposed pus; that it is therefore a putrid infection. Again, it has been maintained that there is a specific pyæmic poison, as there is a specific poison of typhoid fever. The doctrine that certain forms of micrococci play an important part in the causation of pyæmia, possesses much probability, although it is not proven. Investigators are not agreed as to whether these organisms constitute the poison itself, or whether they are generators, or only the carriers of the poison.

We are not sufficiently well informed as to the etiology of either septicæmia or pyæmia, to be justified in drawing a sharp line of distinction between these processes. The presence or absence of metastatic abscesses cannot be considered to prove a difference in the causation of the processes. The possibility, even the probability, that venous thrombi may form in putrid, as well as in purulent, infection, cannot be denied. The resulting emboli, in either case, would be infectious, and, wherever they lodged, they would cause abscesses. Again, there is no apparent reason why the blood may not be poisoned, in so-called purulent infection, without the coincidence of emboli. In view of the possibility of these occurrences, it has been proposed to call putrid infection with multiple abscesses, metastatic septicæmia, and purulent infection without abscesses, pyæmia simplex, in distinction from pyæmia multiplex

[1] Ogston, Archiv f. klin. Chirurgie, Bd. 25, p. 588, 1880.

(Hüter). But the introduction of these terms hopelessly confuses the subject. We cannot, anatomically or clinically, distinguish between metastatic septicæmia and pyæmia, or between so-called simple pyæmia and septicæmia. The difficulties involved in these distinctions are also made evident by the coining of the term septico-pyæmia to designate those cases in which putrid infection is supposed to be combined with purulent infection. In view of these inconsistencies, it seems best at present to include under the name pyæmia those cases of traumatic infectious disease with multiple abscesses, and under the name septicæmia those without abscesses, and to leave to future investigations questions pertaining to differences of causation and to the character of the infectious agents. There are usually differences in clinical history according to the presence or absence of metastatic suppurations.

Wounds and surgical operations, especially those involving bone, are the most common causes of pyæmia. The latter does not occur usually until after suppuration is established. The discharge from the wound becomes thin and scanty, and there is œdema of the surrounding parts. Pyæmia follows also suppurative periostitis and osteo-myelitis, puerperal endometritis, and rarely other internal suppurations. The affections included under the name puerperal fever, embrace both pyæmia and septicæmia. Pyæmia develops most frequently in hospital-wards, and in uncleanly surroundings. Sometimes no apparent cause can be detected. The disease is then distinguished as primary or idiopathic pyæmia.

Especially characteristic of pyæmia is the development of thrombosis of the veins, either within, or in the neighborhood of, the parts affected with suppurative inflammation. These thrombi do not organize, but soften and give rise to infectious emboli. The thrombosis may be accompanied by phlebitis or inflammation of the wall of the vein, but this is not necessary. The emboli (except when the thrombosis is in some of the rootlets of the portal vein) are carried first to the lungs where they cause abscesses which are frequently surrounded by hemorrhagic infarction or lobular pneumonia. Abscesses may be present also in the spleen, the kidneys, the heart, the liver, the muscles, and other parts of the body. These abscesses may be produced by emboli derived either from the primary thrombus or from secondary thrombi formed in the veins near the pulmonary abscesses. There is also reason to believe that secondary abscesses may be formed, independently of thrombi, by the agency of white blood-corpuscles and of micrococci which accumulate in small vessels of the affected part. Suppurative inflammation of the joints and of serous membranes is usually present in pyæmia. Ulcerative or bacteritic endocarditis is sometimes found. There may be inflammation of the lymphatic vessels (lymphangitis) and swelling of the lymphatic glands near the primary source of infection. The spleen is usually swollen, and the same parenchymatous degenerations are present as in other acute infectious diseases. Micrococci have been repeatedly observed in the blood and in the abscesses. Colonies of micrococci in the vessels and in the uriniferous tubes are easily recognized, as a rule, in the early stages of the abscesses in the kidney. The blood usually is well coagulated, and there is less tendency to rapid decomposition than in septicæmia.

The clinical history of pyæmia is characterized by repeatedly recurring chills, more or less pronounced, occurring irregularly, and followed by profuse sweating. Fever is persistent, varying, as shown by the thermometer, in different cases, the greatest amount of heat being directly after the chill, the mercury rising, at this time, from 104° to 108°. The skin becomes sallow, and not infrequently distinctly jaundiced. The intelligence is but little or not at all disturbed. There may be pain in the chest, with cough and frequent respiration; and physical exploration may show pleuritis with effu-

sion, or bronchial râles with broncho-vesicular respiration at different points on either side of the chest, or on both sides. Pain may be felt in the knee and other joints, and effusion within the synovial membrane may be discovered. At length persistent collections, not preceded by the usual local symptoms of phlegmonous inflammation, "cold abscesses," as they are sometimes called, may be found in different situations, sometimes in one or more of the limbs, and sometimes on the trunk. The formation of purulent matter in these situations is sometimes extremely large. Suppurative inflammation of the eye, leading to sloughing and the evacuation of the humors, is an occasional event. This has been observed chiefly in cases of pyæmia following parturition. The affection in most cases runs a rapid course, the duration being from eight to ten days. With less intensity the disease may continue from two to four weeks, and occasionally it becomes chronic, lasting for several months. In the latter case the duration depends on the secondary abscesses which, by their continuance, become properly sequels of the pyæmia. In the vast majority of cases the affection ends fatally. Death seems, in some cases, to be attributable to asthenia incident to the morbid condition of the blood, and sometimes to the secondary affections of the viscera. In the cases which recover, the local effects consist chiefly of subcutaneous purulent collections and arthritic suppuration. The foregoing enumeration of the leading symptomatic events embraces points by means of which, generally, the discrimination of pyæmia can be made without difficulty.

The indications for treatment in pyæmia are essentially the same as in septicæmia.

The prophylaxis embraces disinfectant measures of vast importance, with reference to which surgical treatises are to be consulted.

CHAPTER VIII.

THE CAUSES OF DISEASE, OR ETIOLOGY.

Etiology a branch of General and Special Pathology—Its importance—Internal or Intrinsic and External or Extrinsic Causes—Ordinary and Special or Specific Causes—The terms Contagion, Infection, Miasm, Virus, Venom defined—Other poisons belonging to Toxicology—Traumatic Causes—Spontaneous Diseases—Primary and Secondary Causes—Complications and Intercurrent Diseases—Predisposing and Exciting Causes—Congenital and Inherited Predispositions to Disease—Co-operating or Accessory Causes—Diathesis—Cachexia or Dyscrasia—Endemic Diseases dependent on Emanations from the Soil—Epidemic Diseases produced by Causes existing in the Atmosphere—The Causes of Contagious Diseases exclusively derived from those affected with these Diseases—Fomites—Portability of the special Causes of Diseases not Contagious—The Causes of Contagious and Infectious Diseases probably Living Germs or Organisms—Animal and Vegetable Parasites.

ETIOLOGY is that branch of medicine which treats of the causes of disease. As one of the divisions of the Principles of Medicine, or General Pathology, it treats of causes with reference to diseases considered, not individually, but in groups, or to disease in general. The consideration of the causes of individual diseases forms an important part of special pathology or the practice of medicine. Etiology, therefore, enters into the range of topics belonging to the first and to the second part of the work. Following the

general plan pursued in the foregoing chapters, I shall limit myself here to certain distinctions and definitions which are to be understood as preliminary to entering on the study of individual diseases, deviating from this plan only in making some remarks on the causation of diseases by living organisms.

Knowledge of the causes of disease is important as the basis of prophylaxis or the prevention of disease. It is obvious that in proportion as we are able to trace diseases to their sources, we may expect to extinguish causes or obviate their morbific influence. Knowledge of causes also is important as entering into the management of diseases; for it not infrequently happens that causes continue to be operative after disease has been produced, and their removal is, of course, a prime object in order to effect a cure. It will be apparent, when we come to inquire into the causes of individual diseases, that the amount of our present knowledge in this direction is limited. Modern researches, however, have developed much information, and not a little progress has been made in the prevention of diseases in consequence of increased knowledge of etiology; but there yet remains a wide field for further developments.

Causes are *intrinsic* or *internal*, and *extrinsic* or *external*. Examples of external or extrinsic causes are, infectious miasms, viruses, different poisons, together with the numerous agencies of disease by means of wounds or injuries. On the other hand, examples of internal or intrinsic causes are, an accumulation of urea in the blood, an excess of uric acid in gout, a morbific principle in rheumatism, supposed to be lactic acid, etc.

Among the internal causes belong those which originate in the mind; and these play an important part in the production of morbid phenomena. Overexertion of the faculties of the mind, mental application unduly prolonged, and intense or long-continued emotional excitement, lead to disorders of the nervous system, together with more or less impairment of the vital forces. Insanity and minor forms of mental derangement may not infrequently be traced to these causes. The bodily functions are weakened, partly from direct influences pertaining to the nervous system, and, in part, because the operation of these causes involves neglect of hygienic conditions of health which relate to diet, muscular exercise, recreation, etc. Long-continued mental depression, whether produced by the causes just named, or other causes, often stands in a causative relation to disorders of digestion and anæmia. An absorbing sentiment or passion may induce disorders by leading to neglect of the means of preserving health. Finally, a concentration of the attention on the bodily functions, over-anxiety concerning health, and a craving for the interest or sympathy which illness is expected to awaken in others, are important elements entering into many cases of disease, especially in women. The knowledge and the tact of the physician are often called into requisition in estimating the agency of the various causes referable to the mind.

Causes may be distinguished as *ordinary*, and *special* or *specific*. Ordinary causes are those to which all persons are more or less exposed, and each giving rise to different forms of disease. Atmospherical vicissitudes are ordinary causes. They are generally supposed to be involved very frequently in the causation of disease, and to give rise to a great variety of diseases. Special or specific causes are often extraordinary in their occurrence, that is, persons are exposed to them only at certain times or in certain situations, and each cause gives rise invariably to one form of disease. The causes of typhus, smallpox, etc., are examples of special or specific causes. The cause which produces periodical fever is not capable of producing typhus, that producing typhus will never give rise to periodical fever, and the same is true of other causes belonging in this category. The existence of a special cause may be inferred from the specific character of a disease, although the nature and source

of the causative agent are not understood. It is certain, for instance, that diseases possessing phenomena and laws so distinctive and uniform as those which belong to the clinical history of epidemic cholera, typhoid fever, yellow fever, etc., must each have its own special cause.

In this connection may be defined the terms contagion and infection. For the definitions adopted in the previous editions of this work, are substituted those in accordance with the present use of these terms by medical writers. The term contagion denotes a causative agent (a contagium) produced in a person affected with a particular disease, and capable of giving rise to the same disease when introduced in the body of another person. A contagium may be contained either in a palpable morbid product, for example, the contents of a variolous vesicle or pustule, or in the impalpable emanations from the body. In the former it is said to be *fixed* and in the latter it is said to be *volatile*. A morbid product containing a fixed contagium is called a *virus*. An impalpable emanation containing a contagium is, with etymological propriety, called a *miasm;* but the term miasm is restricted by writers at the present day chiefly to those impalpable causes of disease which originate without the body, and the diseases to which they give rise are distinguished as miasmatic diseases. A familiar example of a miasm is the special cause of the periodical fevers, called malaria; and these fevers are miasmatic diseases. The term infection denotes any causative agent which, under certain conditions, is capable of unlimited increase or multiplication. With this definition, an infectious disease may, or may not, be communicable by means of a contagium. If communicable, it is an infectious contagious disease; if not communicable, it is an infectious miasmatic disease. Liebermeister proposes the name *miasmatic contagious diseases* for those which, as is supposed, require a causative agent produced within the bodies of persons affected, but an agent which it is requisite should undergo certain changes after having been thrown off from the body before becoming capable of giving rise to disease in others. Examples of diseases which are thus distinguished, are typhoid fever and epidemic cholera. The doctrine that the causative agent in contagious diseases is a living germ or organism (contagium vivum), and that this is also true of miasmatic infectious and miasmatic contagious diseases, will be referred to in the concluding portion of this chapter.

A contagious disease may be derived from an inferior animal. Rabies, for example, is derived from the dog or cat, and glanders from the horse. Disease in man may also be produced by the introduction into the system of a product from an inferior animal, which, as regards the animal furnishing it, is a normal product. Such a causative agent is a *venom*. The so-called venomous animals produce, physiologically, an agent which received into the system of man, or of another animal, gives rise to disease. Thus certain serpents and insects have special glands furnishing secretions which cause disease and even death when introduced into the human body. These secretions, normal, as regards the animals which furnish them, are venomous.

Various morbific substances which are neither viruses nor venoms, not giving rise to either contagious or miasmatic diseases, are embraced under the name poisons. They are derived from the mineral and the vegetable kingdom. Their morbid effects are proportionate to the quantity of poison received into the system. Here is a striking difference as contrasted with viruses, the morbid effects of the latter bearing little or no proportion to the quantity received. The number of these poisons is great. Their study constitutes an important branch called *toxicology*. Examples are arsenic, lead, prussic acid, etc. etc. They offer differences as regards the gravity of their morbid effects. Some are quickly fatal in a small quantity, as prussic acid, strychnine, aconite, etc. Others act more slowly and with less virulence, as mercury, lead, etc. None

of these poisons increase within the body, and hence the diseases to which they give rise are not communicable.

The effects of these poisons are manifested in different parts of the body. Certain poisons exert effects on particular parts. Thus, alcohol and opium exert their effects on the brain, arsenic on the intestinal tract, strychnia on the spinal cord, mercury on the mouth, phosphorus on the liver, aconite on the heart, etc. Many, however, act simultaneously on a greater or less number of parts. As regards their effects on the blood, some are merely mixed, or in solution, and act directly on parts to which they are carried in the circulation. Oxalic acid, arsenic, mercury, lead, prussic acid, alcohol, etc., have been discovered in the blood. In other instances chemical combinations take place in the blood. A striking illustration of this is afforded by one of the experiments of Bernard. Emulsin and amygdalin are not poisonous separately, but they combine and form prussic acid. Injected separately into the veins in different animals, they do no harm. If, however, they be successively injected into the veins of the same animal, they combine in the blood to form prussic acid, and the animal dies as if struck by lightning. On the other hand, the blood prevents certain combinations which take place readily out of the body. An experiment of Bernard illustrates this fact. Cyanuret of potassium and lactate of iron in combination form Prussian blue. Injected successively in the veins, they do not combine in the blood, but the combination takes place and Prussian blue is formed after both have entered the urine, or within the intestinal canal.

Certain causes are distinguished as *traumatic;* and this name is applied to distinguish the diseases produced by this class of causes. A traumatic cause gives rise to a local disease by acting in an appreciable manner on the part affected. Traumatic diseases are those thus produced. Anything which occasions an injury or wound of a part, and consequently disease of that part, is a traumatic cause. The name signifies a wound. A bronchitis caused by the inhalation of an irritating vapor is produced traumatically. A calculus in the pelvis of the kidney which gives rise to pyelitis, and a stone in the bladder which occasions cystitis, are traumatic causes. The causes thus distinguished, therefore, may be either internal or external, although in the great majority of cases, they belong to the latter class.

Diseases not traumatic, and which do not proceed from any appreciable causative agency, are said to be *spontaneous.* The term, as thus applied, is to be taken in a conventional, not a literal, sense. It is obviously incorrect to say of any disease that it originated spontaneously. Every disease must have its adequate determining cause. But many diseases are developed without our being able, in the existing state of knowledge, to refer them to their causes; and the term spontaneous, applied to those diseases, means simply that they proceed from causes which are unknown. Pleuritis, pericarditis, and other affections developed frequently in the course of Bright's disease, were formerly considered as spontaneous; but now that their development is attributable to the action of urea accumulating in the blood, the term has ceased to be applicable to them. The number of so-called spontaneous diseases will diminish in proportion as our knowledge of etiology advances.

Causes are distinguished as *primary* and *secondary.* A secondary cause is an effect of disease. Urea, for example, accumulating in the blood, gives rise to various local affections—pleuritis, pericarditis, etc. But the accumulation of urea is an effect of some disease of the kidneys, which interrupts the eliminative function of these organs. Urea in excess in the blood, is thus a secondary cause of disease. A primary cause, on the other hand, does not proceed from a prior disease. All external traumatic causes, for instance, are primary. The same distinction is made among diseases; that is, some

are primary, and others secondary—protopathic and deuteropathic. Primary diseases proceed from primary causes, and those called secondary are due to the effects of pre-existing diseases; in other words, to secondary causes. A large proportion of the diseases, the existence of which is first ascertained, are secondary; they involve in their causation antecedent affections. Not infrequently a number of diseases are thus linked together in a consecutive series. In the examination of patients, therefore, it is not sufficient to have discovered a disease; but, having discovered one disease, it remains to be ascertained whether other diseases do not exist, sustaining to the disease first discovered a relation either of cause or effect. Clinical researches have developed important facts with respect to the causative relations existing between different diseases, and these facts are of great utility in medical practice.

Secondary and subordinate diseases are distinguished as *complications*. A complicating disease is one which occurs in the course of another disease with which it is supposed to have some pathological connection. Pneumonitis, for example, developed in the course of typhoid or typhus fever, is a complication of the latter. Pneumonitis generally has a complication, namely, circumscribed pleurisy. A disease is said to be *intercurrent* when it occurs during the progress of another disease, without necessarily having any dependence on the latter. Lobar pneumonitis, for example, occurring in a patient affected with pulmonary phthisis, is an intercurrent affection.

As just stated, causes of disease may be themselves effects of disease, so that certain diseases may be said to stand in a causative relation to other diseases. On the other hand, some diseases afford protection against others. As an illustration, emphysema of the lungs and pulmonary phthisis may be cited. The latter disease occurs in patients affected with the former so rarely as to show that it exerts a protective influence. Another illustration is afforded by disease of the heart and pulmonary phthisis. A phthisical affection occurs so rarely when cardiac disease occasions much disturbance of the circulation, that the latter must be considered as affording more or less exemption from the former.

Another division is into *predisposing* and *exciting* causes. Predisposing causes induce a liability or tendency to certain forms of disease. Exciting causes, acting on persons already predisposed to certain diseases, determine their occurrence. Predisposing causes may be alone sufficient to give rise to disease, or they may only suffice to place the system in a condition favorable for the occurrence of disease; in the latter case, the disease occurs when exciting are superadded to the predisposing causes. To cite an instance: A person under the influence of predisposing causes is in a condition favorable for the occurrence of acute rheumatism; in this condition he is exposed to atmospherical vicissitudes, and the latter determine an attack of this disease. The exciting cause, namely, the atmospherical vicissitudes, would not, alone, have been adequate to give rise to an attack of rheumatism; and the former, namely, the predisposing causes, alone, might have been inadequate; but, conjointly, they occasion this disease. Exciting causes act the part of the match when everything is ready for an explosion. It is thus seen that predisposing causes determine the nature of the disease, and exciting causes the date of its occurrence.

A predisposition to some form of disease may be inherent in the constitution, or congenital. Some persons have inborn tendencies to certain diseases. This fact is strikingly illustrated by the occurrence of phthisis successively in different members of the same family—a large number of brothers and sisters being carried off by this disease. This congenital predisposition may remain completely latent until the period of life in which the disease is most apt to be developed; and we sometimes see a whole family of children, one after

the other, fall victims to this disease, when they severally reach a certain age. A predisposition to certain forms of disease may not only be congenital, but inherited; a constitution involving a tendency to disease is transmitted from parent to offspring. Among the diseases perpetuated in this way are phthisis, gout, cancer, asthma, syphilis.

The predisposition to a disease, whether congenital or acquired, may be strong or feeble. Various circumstances may act as *co-operating* or *accessory causes;* that is, acting in conjunction with the constitutional tendency. Thus, in a person predisposed to phthisis, the development of this disease may be greatly promoted by unfavorable hygienic circumstances, such as sedentary habits, deficient ventilation, and inadequate alimentation. These co-operating causes, in conjunction with an existing predisposition, may serve to develop the disease, when, without their aid, the predisposition might not have been sufficient. There is reason to believe that persons with a feeble predisposition to this disease often escape, if they be exempt from the operation of co-operating causes. The latter, moreover, are to a greater or less extent controllable, while the predisposition, especially if it be congenital, is beyond control. Diseases thus are preventable, notwithstanding a predisposition to them, in so far as they depend on the union of co-operating causes. Herein lies a truth of great practical importance.

Diseases which originate from special causes often appear to require for their production co-operating causes. Facts seem to show, for example, that yellow fever, periodical fevers, and epidemic cholera, which undoubtedly involve the agency of special causes, would in many cases not have occurred, had not other than the special causes contributed to their occurrence. By eradicating, as far as possible, all unfavorable hygienic influences, special causes may be rendered, to a great extent, or perhaps completely, inoperative. The special causes we may not be able to remove; but co-operating causes are, to a great extent, within our control; and, by removing the latter, the diseases are rendered preventable.

A constitutional predisposition to a particular form of disease constitutes what is called a *diathesis.* A diathesis, therefore, may be either congenital or acquired. And the diseases which are considered as generally, if not always, involving a constitutional predisposition, or diathesis, are sometimes distinguished as *diathetic* diseases. A *cachexia* or *dyscrasia* involves a diathesis, and sometimes more. These terms denote, not merely a constitutional predisposition to disease, but that condition of the system which exists when the disease is actually developed. A person born with a tendency to phthisis, for example, has the phthisical diathesis; and this diathesis eventuates in the tuberculous cachexia when the person becomes affected with phthisis.

The term *vulnerability* has been, of late, applied to a condition of the system favorable for the morbific operation of any causes, either ordinary or specific. The sense of this term differs from that of predisposition, the latter denoting a tendency to a particular form of disease, whereas vulnerability denotes a susceptibility to all morbific agencies. Vulnerability, thus, in contradistinction to predisposition, does not determine the nature of the diseases produced by different causes. The term vulnerability, in fact, means neither more nor less than a general susceptibility to the causes of disease.

Our present knowledge, for the most part, of the special or specific causes of disease, is based on logical inference rather than on demonstration. But certain conclusions respecting their origin and diffusion may be logically determined. One of these conclusions is, that some morbific agents (miasms) emanate from the soil. This may be inferred with respect to the special causes giving rise to diseases called *endemic.* Endemic diseases are those

which prevail within circumscribed territorial limits; that is, their prevalence does not extend beyond sectional boundaries. Now, this fact is sufficient for the inference that the source of the causative miasms is in the soil; because, of the elements which enter into climatic influences, those peculiar to any particular district are terrestrial. Again, in the diseases called *epidemic*, namely, those which prevail successively or simultaneously, at variable intervals, in different and often wide-spread territorial districts, the morbific agents, whatever may be their source, must be transported through the atmosphere, or brought in some way from situations more or less distant. The causes of epidemic disease are migratory. In some instances they traverse successively almost every portion of the habitable globe. This is true of epidemic bronchitis or influenza, and of epidemic cholera. It is altogether improbable that the special causes in these and other epidemics originate in the different sections of country over which their prevalence extends. Diseases are said to be *pandemic* when they are spread simultaneously over a whole country or population. The special causes which give rise to contagious diseases are derived from the bodies of those affected with these diseases; and, with respect to certain of these diseases, it is probable that the special causes are exclusively thus derived. It may fairly be doubted whether smallpox ever originates from any other source, notwithstanding the occurrence of cases in which it cannot be traced to contagion. Yet, the first case of smallpox which ever existed must, of course, have been an exception to this law, and it is possible that there are still occasional exceptions.

Diseases are communicated not only by coming into contact with, or in proximity to, patients, but by means of what are called *fomites*. This term is applied to inanimate substances, such as clothing or articles of merchandise, to which contagious matter has adhered. In this way certain diseases, such as smallpox and scarlatina, may be disseminated at points far distant from the source of their special causes. The term fomites is generally restricted to the transmission of the matter of contagion. But it is certain that other special causes of disease may be transmitted in the same way. Facts, for example, show that the special cause of yellow fever is capable of transportation. And if this be true, it is correct to say that a disease may be *portable*, although not communicable.

Special causes of disease, embraced under the names contagion and infection, have been noticed (*vide* p. 89). The theory most consistent with our present knowledge is, that the essential morbific agents in these causes, are living germs or organisms. This is, by no means, a new theory. The doctrine that the source of epidemic disease is in animalcule life, was advocated many years ago (1839) by Sir Henry Holland, and in a volume by the late Professor J. K. Mitchell, of Philadelphia, published in 1847, were presented facts and cogent arguments in behalf of the cryptogamic origin of malarial and epidemic fevers. Indeed, the theory was advanced very early in the history of medicine, and in modern times was elaborately advocated by the great botanist, Linnæus. More recently, however, the microscopical study of the lowest appreciable forms of life, and discussions relating to the long mooted question as to spontaneous or equivocal generation, have led to the accumulation of weighty evidence in its support; so that the probability of its truth seems vastly greater now than hitherto.

Assuming the causes of contagious diseases to be living germs or organisms, a certain period is required for their development and multiplication within the body sufficiently to give rise to these diseases. In this way may be explained the fact, that for a period which is sometimes extended to weeks, months, and perhaps even years, the special causes remain in the body completely latent as regards any morbid manifestations. The reproduction of germs and organisms

within the body affords an intelligible explanation of the formation of viruses or the morbific agents by which diseases are communicated. The self-limited duration of these diseases is explained by supposing that, after successive generations, the organisms die out, or they are in some way either destroyed or eliminated from the body. The germ theory affords a satisfactory explanation of another fact, namely, that an inappreciable quantity of virus suffices to give rise to the disease of which it is the special cause; and, moreover, that the intensity of the disease bears no proportion to the quantity of virus received. For example, the severest form of smallpox may follow the reception of an almost infinitesimal quantity of virus, while, on the other hand, the disease may be mild after the utmost amount of exposure. In this point of view, these causes are in striking contrast with poisons, the effects of which are in proportion to the quantity received into the system. The experiments of Davaine and others show that if septicæmia be induced in an animal by injecting into the blood a little putrid matter, a still smaller quantity of blood taken from the diseased animal is capable, by inoculation, of producing the disease in another animal, and so, by successive inoculations, the disease may be reproduced in a series of animals. This can hardly be interpreted otherwise than by supposing the immense increase of infective material to denote the multiplication of living organisms.

A remarkable fact relating to the causes of certain infectious diseases is, that, as a rule, they exert their morbid effects but once in the same person. These diseases are rarely experienced a second time. Evidently this is because the susceptibility to the causes is destroyed, since it is not to be supposed that the latter lose their efficiency, and they undoubtedly are received into the system as readily after, as before, the disease had occurred. With our present knowledge, the mode in which the susceptibility to these causes is destroyed, cannot be explained. Assuming the causes to be germs, however, it is well known that the evolution and development of organisms therefrom require certain conditions. The seed must have its appropriate soil, and various circumstances may, on the one hand, promote, and, on the other hand, prevent, its germination. In some incomprehensible mode, these diseases effect a permanent destruction of the unknown conditions, within the body, on which depend the development and multiplication of the germs which, it is assumed, constitute their causes. It should be added that this is not exclusively an effect of diseases which are communicable. Yellow fever, for example, is rarely experienced a second time. Insusceptibility to the causes of contagious diseases is sometimes a natural peculiarity. There are persons who, from birth, and during life, are in no degree affected by the contagium of smallpox, and the same is true with respect to the causes of other diseases. The conditions requisite for the multiplication of certain morbific organisms may exist in inferior animals, and not in man, and *vice versâ*.

Of great theoretical value are experiments intended to shed light on the problem as to the pathogenic properties of bacteria, by the inoculation of the different ingredients of infectious substances. These experiments seem to show in some cases infectious properties both for the soluble or chemical, and for the molecular or bacterial, constituents; but the results are as yet too contradictory to warrant certain conclusions. Nor is it certain in what way bacteria act injuriously; whether by withdrawing from the organism some important constituent such as oxygen (Bollinger); whether mechanically, as irritants, or by occluding a number of small vessels (Hüter), or whether as ferments giving rise to deleterious chemical products (Klebs, Panum, Virchow). To enter into a discussion as to the various experiments, observations, and arguments bearing on this highly important subject, does not fall

within the scope of this work. From what has been stated may be drawn the following conclusions:—

1. That living organisms are active agents in the contraction of all infectious diseases, is a logical inference, explaining better than any other theory, pathological events.

2. This theory appears to have been established by facts in the case of two diseases, namely, malignant pustule and relapsing fever. Reasoning analogically, its application to other infectious diseases is extremely probable.

3. For other infectious diseases, the facts as yet accumulated are not sufficient to demonstrate the correctness of the theory.

Assuming that the germ theory, as applied to all infectious diseases, will hereafter become established, and that our knowledge of the different varieties of morbific organisms, together with the conditions essential to their multiplication within and without the body, will be progressively extended, it can hardly be otherwise than that great changes will be thereby wrought, not only in pathology, but in therapeutics.

Animal and Vegetable Parasites.—The parasites which infest the human body, include both animal and vegetable organisms. Those inhabiting the exterior of the body are called *epizoa*, and those infesting internal parts are called *entozoa*. Some of the parasites are harmless, others cause serious and even fatal disturbance. Parasites may produce injurious effects; *first*, by withdrawing nourishment from the body; *second*, by exciting inflammation; *third*, by mechanical injury. The bacteria may act as organized ferments, or as generators of poisonous substances. The diagnosis of parasitic diseases is to be made usually only by the detection of the parasite. Among the causes which influence the invasion of the human body by parasites may be mentioned geographical situation, the character and mode of preparation of the food, the quality of the water, and the more or less intimate contact into which men come with animals who carry the parasites. There are no grounds for maintaining the doctrine of spontaneous or equivocal generation of parasites.

A. *Animal Parasites.*—The animal parasites belong to the three divisions *protozoa*, *arthropoda*, and *vermes*.

1. The protozoa are the most lowly organized members of the animal kingdom. The *infusoria*, which form a class of protozoa, have been observed frequently in the contents of the intestine, especially in cholera and in inflammatory conditions of the mucous membrane. It has not been proven that they are in any way associated with the cause of disease. The infusoria most frequently found are *cercomonas intestinalis*, *trichomonas vaginalis*, and *paramœcium coli*. The *psorospermiæ*, which have been found in the liver and in the intestinal mucous membrane, are usually classified among the protozoa, but their exact nature is problematical.

2. The arthropod parasites include animals from the subdivisions *arachnida* and *insecta*, which infest usually the skin. To the arachnida belong the *acarus folliculorum*, frequently found in comedos, but without pathological importance, the *acarus* or *sarcoptes scabiei*, which is the cause of the disease known as scabies or itch, the *pentastomum constrictum*, and the *pentastomum denticulatum* which has been frequently discovered in the liver. Under insecta are included the different species of lice, viz., *pediculus capitis*, *pediculus pubis*, and *pediculus vestimenti*.

3. Animals of the division vermes or worms are the most frequent of all parasites. The parasitic worms are embraced under the subdivisions *nematoda* or round worms, *trematoda* or suctorial worms, and *cestoda* or *tæniada*, which include the tapeworms and the old order of cystic worms. *a.* The nematoda are *ascaris lumbricoides*, found often in the small intestine, *oxyuris vermicularis*, vulgarly known as the pin-worm, found in the large intes-

tine, *tricocephalus dispar* in cæcum, *strongylus gigas* in the pelvis of the kidney, *anchylostoma duodenale* in the duodenum, *anguillula stercoralis* in the intestine and bile-ducts in an endemic diarrhœa which prevails in Cochin-china, *trichina spiralis* in the muscles, *filaria medinensis* or guinea-worm in the areolar tissue where it causes painful abscesses (in tropical climates), *filaria sanguinis* found in the tropics in large numbers in the blood; it causes chyluria and hæmaturia. *b.* Under trematoda are included *distoma hepaticum* in the biliary ducts, *distoma lanceolatum* or liver-fluke in the same situation and *distoma hæmatobium* (of Bilharz) in the portal vein and, together with its eggs, in other situations, especially the kidneys, bladder, and intestine, where it may cause severe affections. The distoma hæmatobium is a frequent parasite in Egypt and in Abyssinia. *c.* The cestoda include the fully developed tapeworms and their larvæ or scolices. The immature cestoid worms or scolices, which are parasitic in man, are *cysticercus cellulosæ*, the scolex of tænia solium and the *echinococcus* or hydatid, the scolex of tænia echinococcus, a small tapeworm which infests the dog. Cysticercus cellulosæ may be present in any part of the body. It is of most importance usually in the brain. The echinococcus is most frequent in the liver but it may exist in other parts. The fully developed tapeworms in man are *tænia solium*, *tænia mediocanellata*, and *bothricephalus latus* or Swiss tapeworm. Rare forms are *tænia rara*, *tænia flavo-punctata*, and *tænia cucumerina*.

B. *Vegetable Parasites.*—These embrace the *fungi* and the *bacteria*. The three main fungi of mould, viz., *aspergillus glaucus*, *penicillium glaucum*, and *mucor mucedo*, have been found in diseased, especially necrotic, tissues exposed to the air. It is not known that they can grow in healthy tissues or can cause disease. In a number of diseases of the skin, fungi have been discovered, which constitute an essential pathological element in these affections. These fungi are *achorion Schœnleinii* in favus, *tricophyton tonsurans* in herpes tonsurans, and *microsporon furfur* in pityriasis versicolor. *Oidium albicans* is a fungus present in aphthæ or thrush, a condition found in the mouth and throat, especially of nursing children and of marasmic individuals. *Leptothrix buccalis*, the nature of which is not fully understood, consists of thread-like mycelium. It is present nearly always in the mouth. It does not seem to have pathological significance. The *sarcina ventriculi* forms little cubical cells arranged generally in groups. It has been found in vomited matters, in the feces, and in the gangrene of the lungs.

The living organisms to which the advocates of the germ theory attribute the causation of the infectious diseases, are embraced under the name *schizomycetes*. The term *bacteria* is generally used in the same sense, although it etymologically applies only to the rod-shaped schizomycetes. According to Cohn's classification of the schizomycetes or bacteria, four forms are distinguished; *first*, sphæro-bacteria or micrococci, minute, round granules, the smallest of which appear as mere points under the highest powers of the microscope; *second*, micro-bacteria, small, rod-shaped organisms or cells; *third*, desmo-bacteria or bacilli also rod-shaped, but longer than the former; and, *fourth*, spiro-bacteria, spirochæte or spirilli, spiral-shaped organisms. The bacteria belong to the lowest forms of vegetable life. Under the conditions favorable for their life and growth, they possess an enormous power of reproduction. It has been estimated by Nägeli that a single bacterium in the space of seven to eight hours can give rise to 100,000 individuals of its kind.

The bacteria, which have been found most frequently and in the greatest variety of diseases, are the sphæro-bacteria or micrococci. Their most characteristic appearance is in masses, called colonies or zooglœa, situated in various organs of the body; in the blood or lymph-vessels, in the secreting

tubes, in the tissues or upon free surfaces. Apparently the same forms are present in most decomposing fluids, and investigators have as yet failed to find any differences of form in the micrococci present in a great variety of diseases, such as diphtheria, erysipelas, pyæmia, ulcerative endocarditis, pyelo-nephritis, variola. To the second group, the micro-bacteria, belongs the small cylindrical form, called bacterium terms, which is present in all decomposing fluids, and which is regarded by Cohn and Pasteur as the ferment causing putrefaction. Of the group of bacilli, the one which has the greatest pathological importance is the *bacillus anthracis*, which has been proven to be the infectious germ of malignant pustule or splenic fever. The spirillum tenue, also called spirillum Obermeieri, from its discoverer, appears as a delicate spiral thread, and is always present in the blood during the febrile paroxysms in relapsing fever.

While all microscopical observers now admit the frequent, if not constant, presence of bacteria in most infectious diseases, they are not agreed as to the pathological importance of these organisms. The demonstration of the germ theory requires, 1st, the proof afforded by direct observation of the existence of germs or organisms in the blood or tissues; 2d, that certain living forms are always present in connection with certain diseases; 3d, that these forms are not to be found in the blood or tissues when the diseases do not exist, and 4th, that the inoculation of the specific germs of a disease shall produce the same disease in another individual. As regards the disease called malignant pustule,[1] these requirements have been fulfilled by the researches and experiments of Pollender, Brauell, Davaine, Koch, Bollinger, and others. Wagner has discovered that the infection by the bacilli anthracis may take place through the respiratory or the intestinal tract, as well as through the skin, producing a form of intestinal mycosis. So, too, for relapsing fever the conditions necessary for the establishment of the spirillum of Obermeier as the infecting germ of the disease have been met, although the investigations are less complete than in the case of malignant pustule. While, then, we may regard the germ theory as established for these two diseases, important links in the chain of proof are missing as regards the other infectious diseases. Among the objections to be met before the theory of a living contagium can become a settled truth for these diseases, are, 1st, the apparent identity in form of the bacteria observed in so many different diseases; 2d, the alleged inconstancy of their presence in different cases of the same disease; 3d, the appearance of seemingly identical forms in the living body, and in decomposing substances; 4th, the absence of information as to the specific properties of the organisms found in a given disease. As regards the first objection it may be replied that the organisms concerned are so exceedingly minute as to render it very difficult to detect slight variations of form, that in some instances differences have been discovered where none had previously been found, and, finally, it has been rendered highly probable that identity of form by no means involves identity of properties or functions. We are not to attribute too much importance to failure in finding the suspected organisms in certain cases, for, in consequence of their extreme minuteness, it is almost impossible to recognize many of them except in masses or colonies. Moreover, Koch has recently shown that special methods of investigation, such as a peculiar mode of illumination and of staining, are often required for their detection. It was formerly supposed that many cases of malignant pustule occurred without the presence of the specific germ, but Koch has demonstrated that the elongated and easily recognized baccilli produce minute spores of equal virulence and greater tenacity of life, which had previously escaped observation.

CHAPTER IX.

SYMPTOMATOLOGY. DIAGNOSIS. PROGNOSIS.

Pathognomonic Symptoms—Diagnostic Symptoms—Subjective and Objective Symptoms—Signs—Clinical History of Diseases and the different Modes by which it is obtained—Stages of Disease—Precursory or Prodromic Events—Sequels—Diagnosis—Reasoning by way of exclusion—Differential Diagnosis—Prognosis—Prognostics.

THE study of the symptoms of disease forms a division of the principles of medicine, or general pathology, called *Symptomatology* or *Semeiology*. The consideration of symptoms will occupy a large proportion of the space to be devoted to each individual disease, in treating of the practice of medicine, or special pathology, in the second part of this work. It will suffice to present in this chapter certain distinctions and definitions which should be understood before entering on the study of individual diseases.

Under the name symptoms are embraced all appreciable morbid phenomena occurring in connection with disease. The name signifies to fall together, and denotes concurrence of events. To repeat the often quoted comparison by Galen, symptoms accompany diseases as the shadow follows the substance. By means of symptoms the existence of disease is made apparent, and the character and seat of different affections are ascertained.

Certain symptoms are distinguished as *pathognomonic*. A pathognomonic symptom is one which denotes invariably the existence of a particular disease. It derives this significance from the fact that it occurs only in connection with one disease. Whenever such a symptom, therefore, is present, it represents that disease, and, in itself, suffices for its recognition. The number of pathognomonic symptoms is quite small. As an illustration, a semi-transparent, viscid, rusty-colored matter of expectoration belongs exclusively to pneumonitis. It is, therefore, a pathognomonic symptom, always denoting the existence of that disease. In like manner the crepitant râle, obtained by auscultation, is so distinctive of the same disease as to be nearly pathognomonic. It would be difficult to cite many additional examples.

A symptom is said to be *diagnostic* when it occurs more frequently in connection with a particular disease than with other diseases. Just in proportion as it is restricted to a few diseases, is its diagnostic import marked; that is, it denotes the presence of some one of these diseases, and its value in diagnosis is the greater the smaller their number. Different symptoms differ as regards their respective diagnostic value. Some are highly diagnostic; in other words, they point strongly to the existence of particular diseases. Others are moderately, and, again, others slightly diagnostic. The measure of diagnostic significance depends on the frequency of concurrence with a particular disease and the infrequency of concurrence with other diseases.

Symptoms are either *subjective* or *objective*. Subjective symptoms are those which relate to the sensations or feelings of the patient, and which, consequently, the physician can appreciate only through the patient's description of them. Objective symptoms, on the other hand, are those which the physician observes for himself, and for a correct appreciation of which he is in no wise dependent on the patient. As regards subjective symptoms, the

physician is exposed to error in consequence of inability on the part of the patient to describe them clearly. In young children this class of symptoms is not available. This is true, also, of idiots, the insane, and in the delirium incident to different diseases. As regards these symptoms, too, the physician is liable to be deceived by intentional misrepresentations on the part of patients; and he is liable to be deceived, unintentionally, by a tendency, on the one hand, to exaggeration, and, on the other hand, to depreciation of morbid sensations or feelings. Owing to these sources of error, much tact is often requisite in placing a proper estimate on subjective symptoms. Objective symptoms are not open to the same liabilities to error. The physician judges of these by the exercise of his own senses, and, if he fail to discover or place a proper estimate upon them, the fault consists in his own want of attention, judgment, or skill. Objective symptoms, thus, are much more reliable than subjective, in the investigation of cases of disease.

The exaggeration of pain or suffering of any kind, and of morbid sensations, is common, sometimes because patients are led to form an exaggerated idea of their subjective symptoms; sometimes with a view to awaken interest or sympathy; sometimes for malingering purposes, and sometimes to secure greater attention on the part of the physician and more efficient treatment. Factitious and exaggerated ailments enter pretty largely into the cases which the practitioner is called upon to treat.

A symptom, as already defined, is any manifest morbid phenomenon or event. Occurring concurrently with a disease, it may, or may not, have a pathological connection with that disease. Its pathological connection with the disease may be such as to render it a pathognomonic symptom, or more or less diagnostic; and, on the other hand, it may be present as a mere coincidence. If the latter be true, it has no pathological connection with the disease, and is devoid of diagnostic significance. This difference among symptoms has been expressed by calling them *signs* when they are either pathognomonic or more or less diagnostic. According to this distinction, a symptom becomes a sign whenever it denotes, in a greater or less degree, the existence of a particular disease. The term signs, however, has come conventionally to be used in a different sense. It is usual to apply this term to the phenomena obtained by certain methods of investigation distinguished as physical, namely, percussion, auscultation, etc. These phenomena are called physical signs, but for convenience, the word physical is often omitted, and is considered as understood when the term sign is alone used. In this sense of the term signs, it is used in contradistinction to symptoms, the latter embracing all other phenomena manifested in connection with disease. The phenomena thus included under the name signs, are, of course, objective, and will be found to be the most reliable of those by means of which the existence, seat, and character of certain diseases are ascertained.

Among the physical methods of examination introduced into modern medicine, the use of the thermometer holds an important place. For measuring the heat of the body, a thermometer adapted to this purpose is requisite. A self-registering thermometer is to be preferred. The bulb of the instrument is to be placed deep within the axilla, and the arm of the patient folded across the chest, the perspiration having been first wiped away. The instrument should remain in this situation for eight or ten minutes. It is a good practical rule to allow the thermometer to remain until a minute passes without any further rise of the mercury, the physician pressing the shoulder of the patient in order to secure close contact of the integument on all sides of the instrument. The normal temperature is from 98° to 99° Fahr. in the great majority of persons; exceptionally it may be half a degree, or even a little

more, either above or below the range. The normal fluctuations are inconsiderable in comparison with the variations incident to certain diseases.

The diurnal variations in health are as follows: The temperature is at its minimum at about 6 o'clock A. M.; the maximum is reached late in the afternoon, and then there is a fall which lasts until 6 A. M. The range of the ordinary diurnal fluctuations is not greater than about one and a half degrees, Fahrenheit. Exercise may cause considerable rise. Food causes a rise which is most marked after breakfast, less so after lunch; and after dinner there is a retardation of the fall which would otherwise occur. Alcohol diminishes somewhat the temperature. Tea causes an elevation.

As a means of ascertaining with accuracy the animal temperature, the clinical thermometer is indispensable. The sensation communicated to the hand placed on the skin, on which physicians heretofore relied for ascertaining the heat of the body, is not to be depended upon; the thermometer in the axilla may indicate an increase of heat, when, to the touch, the surface of the body does not seem to be warmer than in health. Still less reliable are the sensations of the patient; he may complain of coldness when the thermometer indicates increase of heat, and *vice versâ*. By means of the thermometer, symptoms pertaining to animal heat are rendered objective, and determined with precision. The axilla is a much better situation in which to place the bulb of the instrument than under the tongue, and a properly constructed instrument may be conveniently applied in that situation. In some instances however, it is necessary to introduce the bulb of the thermometer into the rectum or vagina. As a rule the body heat, ascertained in these situations is about a degree higher than the axillary temperature.

The study of the thermometric phenomena in different diseases has developed certain laws, the more important of which may be here stated.

In fevers and other acute diseases, the temperature of the body, as indicated by the thermometer, is always more or less raised, thus substantiating the propriety of the term fever, which signifies increase of heat. If the thermometer do not indicate preternatural heat, it is certain that a patient is not in a febrile state. Hence the physician, by means of the thermometer, may be enabled to avoid an error into which he might be led by other symptoms pointing to the existence of a fever or some acute disease. On the other hand, increased heat sometimes precedes other evidence of a febrile disease which may thus be predicted by means of the thermometer.

The increase of heat in different febrile diseases very rarely exceeds 110° Fahr., and, as a rule, the amount of increase is a criterion of the intensity of the disease. An increase to 100° or 101°, is evidence of mildness of the disease. If the thermometer indicate steadily 105° Fahr., it is certain that the disease is severe. A persisting temperature above 105° denotes great danger, and an increase to 108°, 109°, or 110° Fahr. is usually a fatal sign.

The persistence of preternatural heat in any disease denotes its continuance. Whatever may be the symptoms, the career of the disease is not ended as long as the thermometer indicates an abnormal temperature. A progressive increase of heat from day to day denotes a corresponding increase of the severity of the disease, and the reduction of heat to the normal standard, as a rule, is evidence of convalescence. The temperature, in some diseases, falls rapidly to the normal standard, and in other diseases the decline is gradual. The term defervescence denotes the decline of temperature toward the standard of health, meaning, generally, the approach of convalescence. Some diseases are characterized during the period of defervescence by considerable oscillations of temperature between night and morning, the maximum being generally at night and the minimum at morning. Typhoid fever

is especially characterized by these oscillations toward the end of the febrile career. Hence it is important to employ the thermometer, not only daily, but at least twice a day. The decrease of heat in the morning is favorable, whereas, an increase from night to morning is the reverse. The temperature in some cases of disease remains above the normal standard after the general symptoms denote convalescence; under these circumstances, the patient is in danger of a relapse or the supervention of some other affection. A relapse or the supervention of some other affection is denoted by a rise of temperature after either apparent or real convalescence. During the progress of a fever or any acute disease, a sudden notable increase of temperature, not sufficient to denote impending death, points to the development of some complication or intercurrent affection.

The abnormal variations of temperature which are most apt to occur consist of more or less increase. Diminution below the normal standard is comparatively rare, and has less significance; yet the latter occurs occasionally, and is not without importance. In the course of typhoid fever a sudden and notable decrease of temperature may denote the occurrence of intestinal hemorrhage. In some cases of disease the temperature is observed to fall notably without improvement in other symptoms, constituting, under these circumstances, an unfavorable symptom. In the collapsed stage of epidemic cholera the heat falls three or four degrees below the normal standard. In conclusion, while the thermometer enables the practitioner to obtain important information concerning diagnosis and prognosis, this information is always to be considered in connection with other facts belonging to the clinical history, and the significance or value of the thermometric phenomena depend, in no small measure, upon the symptoms with which they are associated.

From time immemorial morbid characters of the arterial pulse have been ranked among the most important of objective symptoms. The *sphygmograph* represents to the eye the movements of the pulse. Applied over the radial artery, a line traced in an upward direction represents the influx of blood from the systole of the left ventricle; from the summit of this line, a line downward and more or less oblique, represents the efflux of blood from the arterial system into the capillaries. The two lines connected at the summit make a diagram called by Marey the form of the pulse. The upward line traced during the ventricular systole is called the *line of ascent;* the oblique line traced from above downward during the ventricular diastole is called the *line of descent*, and the junction of the two lines at the top is called the *summit.* The number of these diagrams within a given space, of course, shows the frequency of the pulse. Pulse-writing thus consists of a series of diagrams, each representing an arterial pulsation, that is, the movements occurring from one beat of the heart to another.

Comparative observations by Marey and others, have shown that the form of the radial pulse has certain traits as regards the line of ascent, the line of descent, and the summit, which are physiological, that is, they belong to health, and that certain variations in the form of the pulse are pathological, denoting morbid conditions relating to the circulation. These pathological variations constitute characters symptomatic of disease. Referring the reader to other works for an account of the mechanism of the sphygmograph, the rules for its employment, and illustrations of the varied forms of the pulse in health and disease, the more important of the characters which have been ascertained will be here concisely introduced. The characters relate respectively to the line of ascent, the descent, and the summit.

The line of ascent represents, measurably, the force of the systole of the left ventricle. Other things being equal, the length of this line is a criterion of the force with which the blood is propelled into the aorta. The length of

this line is, however, much affected by the resistance caused by the tension of the arteries, or, in other words, the amount of blood which the arteries contain at the time of the ventricular systole. In proportion as the tension is great, that is, the arteries filled, the line will be short, although the ventricular systole be strong; and, on the other hand, the line is long in proportion as the tension is small, that is, the arteries unfilled, provided the heart's action be not weak. Bloodletting increases the length of this line, not by increasing the power of the heart's action, but by diminishing the arterial tension. Notable shortness of this line is observed if the heart's action be much enfeebled, as in an advanced stage of typhoid fever, or in cases of local inflammation in connection with a typhoid condition. The line is notably short and varied with successive pulsations in cases of mitral cardiac lesions with much insufficiency. A notable disparity in this regard between the two radial pulses exists in certain cases of aneurism affecting the aorta, the innominata, or the subclavian artery.

The line of ascent is either vertical or more or less oblique. If vertical, it denotes quickness of the contraction of the left ventricle; and in proportion to the obliquity the ventricular contraction is slow. A vertical line of ascent, representing rapidity of the arterial movement, denotes a character of the pulse which, to the touch, may give a fallacious sensation of force. The shortness of the line may show want of force when, owing to the quickness of the movement, the pulse appears to be strong.

The line of ascent is not always a straight line, but being for a certain distance either approximately or completely vertical, it then becomes more or less oblique, or the obliquity is increased. This denotes a difference between the first and latter part of the ventricular systole, as regards quickness—at the beginning it is more or less quick, and towards the end, owing to the resistance of the blood in the arteries, it becomes more or less slow. The change is sometimes sudden, and causes a jog or notch toward the upper extremity of the line; this is observed in some cases of aortic cardiac lesions involving obstruction and regurgitation.

The line of descent represents the arterial movements from the cessation of one ventricular systole to the time when the next systole occurs. In general, no movement of the artery is appreciable by the touch during this period. The sigmoid valves of the aorta being closed, the movements of the artery correspond to the efflux of blood from the arteries into the capillaries. The line of descent connects the two succeeding lines of ascent extending from the upper end of one to the lower end of the other. The length of this line will thus depend on the interval of time between the ventricular contractions, that is, on the frequency or infrequency of the pulse. The line is more or less oblique according to the rapidity or slowness with which the efflux of blood from the arteries into the capillaries takes place. The line is sometimes straight and sometimes curved, the convexity looking upward. Morbid characters relating to obliquity and curvature are produced by an abnormal obstruction in the capillary system, and by an abnormal rigidity of the coats of the large arteries.

The line of descent in health has in its course an oscillation more or less marked corresponding to the dicrotic or rebounding pulsation which is sometimes felt by the touch in cases of disease. The sphygmograph shows dicrotism to be a normal character of the pulse, but the rebounding or oscillation, in health, is not sufficient to be felt by the finger. When appreciable by the touch, it is abnormally increased. The dicrotic character of the line of descent is marked in proportion as the ventricular systole is rapid, as denoted by a vertical line of ascent; and, on the other hand, the dicrotic character is slight if the contraction of the ventricle be slow, as denoted by obliquity

of the line of ascent. Elasticity of the arterial coats is necessary to the presence of dicrotism in a marked degree; in cases of senile rigidity of the arteries it is either lost or but slightly apparent. Slowness of the efflux of blood from the arteries into the capillaries, inducing slowness of the ventricular contraction, diminishes, whereas relaxation of the capillaries, by increasing the freedom of this efflux, increases, dicrotism. The dicrotism is more marked when the quantity of the blood sent out with the ventricular systole is small, than when the quantity is large. Dicrotism is especially marked in continued fever, a fact which Marey attributes to the relaxation of the capillaries. In some cases of disease two or more oscillations may appear in the line of descent, showing a corresponding number of oscillations in the artery during the ventricular diastole. This occurs under circumstances favoring dicrotism, when the frequency of the pulse is notably diminished.

Certain characters relate to the summit, that is, to the connection between the upper end of the line of ascent and of the line of descent. The line of ascent ends when the ventricular systole is balanced by the resistance caused by the blood in the arteries and the arterial coats. Now, if the systole end directly this equilibrium takes place, and the efflux of blood into the capillaries at once begins, the line of descent forms with the line of ascent an angle more or less acute; in other words, there is no intermediate space at the summit. If, however, the ventricular systole continue after the equilibrium is established, the summit is a plane of variable length. If the equilibrium be exact, the summit is represented by a line perfectly horizontal, its length representing the time between the cessation of the influx of blood into the arteries and the commencement of the efflux into the capillaries. If the equilibrium be not exact, the line forming the summit will not be perfectly horizontal; it will have an inclination upward if the influx slightly exceed the efflux, and, if the reverse, the line will incline downward. The extension of the ventricular systole beyond the ending of the line of ascent, as denoted by a line nearly or quite horizontal at the summit, occurs especially in connection with senile induration or calcification of the arteries.

The study of the graphic characters of the pulse has afforded important information concerning the circulation both in health and in disease. The sphygmograph has enlarged our resources for obtaining data for diagnosis and prognosis. The delicacy of the instrument, however, the nicety required for its employment, and the numerous incidental circumstances which are liable to affect its operation, restrict its availability in the hands of the general practitioner.

The ophthalmoscope has added an important field to the domain of symptomatology. Aside from the study of the diseases of the eye, the ophthalmoscope brings under observation morbid appearances which are important as symptoms of extra-ocular morbid conditions. Certain of these morbid appearances relate to the vessels of the retina and the optic disk. Congestion or hyperæmia of these vessels, on the one hand, and, on the other hand, a deficiency of blood, or anæmia, to a certain extent represent corresponding morbid conditions of the nervous centres. An extravasation of blood into the retina may denote, under certain circumstances, changes of the intra-cranial vessels, involving liability to cerebral hemorrhage. Characteristic intra-ocular appearances have repeatedly led to the discovery of renal disease which had previously been unsuspected. Appearances denoting inflammation of the optic nerve and the retina, sclerosis and atrophy, are significant, in certain cases, of intra-cranial or intra-spinal diseases. On the other hand, the absence of morbid appearances within the eye is sometimes of importance as contributing to exclude lesions or inflammatory affections of the nervous centres. It is a noteworthy fact that observation by means of the ophthalmo-

scope may show significant intra-ocular morbid appearances when there is neither defect of vision nor any subjective symptoms referable to the eye. The careful study of the morbid appearances which are observed in different diseases, in connection with other symptomatic phenomena and post-mortem examinations, for a longer period, is necessary to determine the full amount of reliable information to be obtained from this source. It is certain, however, that the ophthalmoscope is a highly important acquisition of modern clinical medicine as a means of investigating, especially, diseases of the nervous system with reference to diagnosis and prognosis, sustaining, in relation to these diseases, in some measure, at least, the same relation as the stethoscope to the affections within the chest. In treating of the diseases of the nervous system, in the second part of this work, the symptoms furnished by the ophthalmoscope, according to the observations of those who have devoted attention to this field of clinical study, will be noticed. To distinguish with accuracy the varied morbid appearances which are to be observed by means of this instrument, requires an amount of skill which can only be obtained by giving to its use special attention, and by considerable experience. The student or practitioner who desires to become a skilful ophthalmoscopist should, if practicable, obtain practical instruction from an expert, and he will, of course, consult works which treat *in extenso* of ophthalmoscopy.[1]

The symptoms and signs which occur during the course of a disease, are the events which make up its *Clinical history.* This phrase is applied to a description of the manifest phenomena taking place from the beginning to the end of a disease, together with the order of their succession and the laws which govern them. Or, instead of clinical history, it is proper to say the *natural history* of a disease, when the disease is allowed to pursue its course unaffected by disturbing influences of any kind, and when no attempt is made to arrest, abridge, or modify its course by therapeutical measures.

How is the clinical or natural history of a disease to be obtained? There are three methods which may be employed. One method consists in selecting, as types of the disease, a few well-marked cases, and basing the description of the disease on the events observed in these cases. This method is defective, because some symptoms belonging to the disease might be wanting, and some symptoms not belonging to the disease might be present in these few representative or typical cases. Moreover, this method is inadequate to show the relative importance of particular symptoms. Another method is to make out a history from recollection, after having observed a greater or less number of cases. A history thus obtained must be imperfect from the obvious inability to retain in the memory all the events which occurred while the cases were under observation, together with the order and relative frequency of their occurrence. The third method is the only one by means of which an accurate clinical history of a disease is to be obtained. It consists, *first*, in the accumulation of a certain number of cases fully and carefully recorded; and, *second*, in an analysis of the recorded cases with reference to the symptomatic phenomena which occurred, the relative frequency of their occurrence, the order of their succession, the number of deaths and recoveries, the duration of the disease, etc. By this method are ascertained events which are constantly present, and, therefore, have an essential relation to the disease; events which are incidental to the disease, being present more or less frequently, and events the presence of which is purely accidental. There are many diseases which have not, as yet, been sufficiently studied after this

[1] The work by Dr. Allbutt "On the Use of the Ophthalmoscope," etc., is the fullest on this subject in the English language. Dr. A. treats of the subject with commendable caution and candor. *Vide* Traité iconographique d'Ophthalmoscope par N. Galezowski, Paris, 1876.

method, and here, therefore, is ample scope for further clinical labor. Among the diseases which have been studied after this method may be mentioned typhoid and typhus fever and acute lobar pneumonitis. The knowledge of the clinical history of these and some other diseases obtained by means of this method within late years exemplifies its advantages.

The clinical history of a disease is divided into several distinct periods or stadia, which are commonly called *stages*. The first stage may be distinguished as the invasion or access of the disease. This period dates from the first morbid manifestations, and extends to the time when the disease may be considered as fully developed or established. The duration of this stage varies in different diseases and in different cases of the same disease. Generally the duration is governed by certain laws proper to different diseases. Some diseases are characterized by the abruptness of their development, the stage of invasion being very short or altogether wanting. The *career* or *course* of a disease extends from the date of its development, that is, from the end of the stage of invasion, to the time when the disease may be considered as ended. This period is frequently subdivided into two or more stages. The stage of convalescence embraces the period between the end of the disease and the complete restoration of health.

The clinical history of a disease properly embraces phenomena which may precede the stage of invasion or access. They are distinguished as *precursory* or *prodromic* events; and in some diseases is to be included a period which is called the period of *incubation*. The latter term, signifying hatching, relates to the time which elapses after the reception of certain special causes of disease, before any morbid manifestations take place. For example, after inoculation with the virus of smallpox, a certain number of days elapse before any morbid phenomena make their appearance. But, in the mean time, occult operations are going on in the system, and, when these are sufficiently advanced, the period of invasion or access occurs. The significance of the term incubation is thus apparent. It is rendered especially significant by the germ theory of the causation of many diseases. The existence of a period of incubation is one of the points in evidence of the truth of this theory. Again, the clinical history of a disease should take in phenomena which may occur after recovery from a disease, provided they are dependent upon it. Certain diseases are liable to be followed by certain consequences, which are called *sequelæ* or *sequels*. Thus, after recovery from scarlatina, albuminuria and general dropsy occur in a certain number of cases. These are results of this disease, and hence belong to its history as sequels. In like manner phthisis is apt to be a sequel of measles, motor paralysis follows diphtheria, etc.

As a general statement, diseases, in respect of the phenomena and laws belonging to their natural history, present in different times and places great uniformity; they are essentially the same in different parts of the world, and they undergo little or no material changes from age to age. This statement is believed to be correct, although it is in opposition to views somewhat prevalent. The different phases and modifications which the same diseases may present, not only at different times and places, but in different cases at the same time and place, are, for the most part, to be explained by the coexistence of affections which may have been antecedent or which are developed as complications.

Diagnosis.

One of the most important of the aspects under which individual diseases are to be considered, is their *diagnosis*. The term diagnosis means the dis-

crimination of diseases, that is, ascertaining their character and seat. The practical importance of a correct discrimination of diseases, with reference to their management, is sufficiently obvious. How is it possible to bring to bear upon a case of disease established principles of treatment, until the character and seat of the disease are ascertained? Diagnosis and treatment are, in fact, the two practical ends of the study of medicine. Diagnosis is also important with reference to obtaining knowledge of the clinical history of diseases. In collecting cases for analysis, if different diseases be confounded, the results of the analysis will be vitiated. In like manner, correctness of diagnosis is the basis of therapeutical experience. Conclusions drawn from the effects of measures of treatment in a series of cases will, of course, prove fallacious if the series include cases of different diseases which have been confounded. Here is a source of not a little of what has been called false experience in practical medicine. Diseases which were formerly confounded are now known to be distinct and readily discriminated from each other. For example, the eruptive fevers, measles, scarlet fever, and smallpox were once considered as different varieties of one disease. Physicians did not undertake, until within a few years, to discriminate between pleuritis, pneumonitis, and bronchitis; now the diagnostic characters of each are well ascertained, and are sufficient for its recognition. Still more recently, typhus and typhoid fever have been shown to be essentially distinct diseases.

Differences in skill and tact, among practitioners of medicine, relate especially to diagnosis. In medical consultations it is here chiefly that points for discussion and disagreement arise. It is here that the want of aid and counsel is oftenest felt by the physician. The diagnosis involves more embarrassment than the management of diseases. This fact is not appreciated by the people at large, many of whom undertake to decide respecting the nature and seat of the disease whenever their friends are ill.

The diagnosis of a disease may be based on the presence of a pathognomonic event. Thus, the characteristic expectoration, or the crepitant râle, denotes the existence of pneumonitis. But, as already stated, there are but few symptomatic phenomena which are truly pathognomonic. Moreover, they are not present in all cases of the diseases which they denote if they be present; hence their absence is by no means proof against the existence of the diseases. The characteristic expectoration and the crepitant râle, for example, are wanting in not a very small proportion of cases of pneumonitis. It is evident, therefore, that the diagnosis of a disease cannot often be based on pathognomonic events. And, next in importance, as regards the basis of diagnosis, is the presence of diagnostic symptoms. As a rule, in proportion to the degree of diagnostic significance belonging to the symptoms present and their number, is the diagnosis of a disease easy and positive. In these respects different diseases and different cases of the same disease differ widely; in some instances the diagnostic symptoms present are few in number and weak, while in other instances they are many and strong. It is with special reference to the relative diagnostic value of the different events which make up the clinical history of a disease, that this history is important to the physician.

The laws of disease are often of importance in relation to diagnosis. For example, typhoid fever rarely affects persons over fifty years of age. When, therefore, persons beyond this period of life are said to have typhoid fever, the chances are that an error has been made in diagnosis. Certain diseases, as a rule, occur but once in the same person. The probabilities, therefore, in a case of doubtful diagnosis, are against the existence of a disease of this class, if it be ascertained that the patient has already had the disease. Certain physical signs situated within a circumscribed space at the summit of the

chest, denote phthisis, while the same signs, situated elsewhere, might point to some other affection, owing to the law that a phthisical affection, in the vast majority of cases, first occurs at or near the apex of the lung. Similar illustrations might be multiplied; the laws regulating the development of a disease, the succession of events, its duration, its sequels, etc., often furnish valuable aid in its diagnosis. Here, too, the practical importance of knowledge of the clinical history of diseases is apparent.

A highly effective method of reaching the diagnosis of a disease is called "reasoning by way of exclusion." In a case of doubt as regards diagnosis, the problem is generally to decide between a certain number of diseases. The existing disease is one of two, three, or more diseases which may be suspected to exist. Now, if it be difficult to decide which one of these is the existing disease from the positive proof relating to diagnostic events and laws, it may be practicable to decide that there is insufficient evidence of the existence of one or more, and therefore the latter are excluded. By this process of elimination the number of diseases is diminished, and may be reduced even to one disease; the diagnosis then being made on the principle of exclusion. To illustrate the application of this method, the presence of lancinating pains in one side of the chest, as a prominent symptom of disease, is consistent with the existence of either pleuritis, pneumonitis, or pleurodynia. The question is, which one of these three diseases is the existing disease. In seeking to decide this question, we look for positive evidence of the existence of either one, that is, for pathognomonic or diagnostic symptoms. The characteristic expectoration of pneumonitis would be decisive, if present, but its absence is not proof that this disease does not exist. We cannot exclude this disease by the absence of that symptom. But pneumonitis is frequently accompanied by a crepitant râle, and always leads to solidification of lung, which is revealed by certain auscultatory signs. Suppose these signs to be wanting, we may exclude pneumonitis. The question is now between pleuritis and pleurodynia. Pleuritis is sometimes accompanied by a friction murmur on auscultation, and always, if primary, leads to more or less liquid effusion, the presence of which is demonstratively determined by physical signs. Suppose these signs to be wanting, we may exclude pleuritis. We thus arrive, by way of exclusion, at the diagnosis of pleurodynia, assuming the problem to comprise only these three diseases.

In discriminating a disease from one of several diseases with which it has more or less symptomatic phenomena in common, the amount of positive evidence in behalf of its existence is to be considered, and, also, the evidence against the existence of the diseases from which it is to be discriminated. This comparison of one disease with other diseases, with reference to the positive and negative evidence of its existence, constitutes what is called *differential diagnosis;* and to discriminate a disease in the manner just described is to differentiate it. Thus, typhus and typhoid fever have many symptoms in common, but differ from each other in essential points. The differential diagnosis of these diseases has reference to the circumstances which denote the presence of one, and the absence of the other.

Diagnostic skill is required, not alone in differentiating diseases, but in the discrimination of cases in which diseases are either simulated or their existence fancied. The knowledge and tact of the physician are here not infrequently called into requisition. The judgment must rest mainly on deviations from the established laws of different diseases as regards symptomatic phenomena, etc., and the absence of objective phenomena which in certain diseases are invariably present. It follows, that the practitioner, other things being equal, will be successful as a diagnostician in such cases, in proportion to the accuracy and extent of his knowledge of the phenomena

and laws of different diseases. Diseases are simulated for the attainment of certain ends. Thus, soldiers feign diseases with a view to escape active duty, or to obtain a discharge from the service; prisoners feign diseases to secure pardon, or the comforts of a hospital; and cases are not rare of persons simulating various affections to excite sympathy and become objects of interest. Feigning diseases for these or other ends is called malingering, and persons attempting the deception are malingerers. One mode of malingering is to pretend that diseases which actually exist are more severe than they really are. Among the diseases which malingerers are apt to feign are, epilepsy, paralysis, phthisis, aphonia, amaurosis, and insanity.

Practical skill in diagnosis requires mental qualifications which all do not possess in equal measure. Aside from these, the amount of skill which may be acquired will be proportionate to the knowledge of, and familiar acquaintance with, different diseases as regards their clinical histories. It would be absurd to suppose that diseases are to be recognized by an intuitive perception, and that some persons have a peculiar innate gift in this direction. A diagnosis not based on adequate pathological information is always open to more or less of the chances of error which pertain to guessing. The mental qualifications of the skilful diagnostician do not differ essentially from those required for other than medical investigations, namely, accuracy of observation, the ability to reason correctly, sound judgment and good sense.

Prognosis.

The division of medicine called *prognosis* treats of the means by which the course and termination of diseases may be foreseen. It is often important to form a correct judgment concerning the way in which diseases may be expected to end, with reference to communications with patients and their friends. They may desire, and, if so, it is proper they should receive, information on this point. Nor should the physician be unmindful of the fact that people in general are apt to estimate his knowledge and ability by the correctness of his judgment in this regard. Recollecting this fact, the protection of his own interests, in addition to other considerations, will dictate a certain amount of reserve in his predictions. But a correct judgment as regards prognosis may be important with reference to treatment. Therapeutical measures are sometimes to be withheld in view of the complete hopelessness of the condition of the patient; and, under these circumstances, persistence in the use of remedies is not only superfluous, but likely to do harm. On the other hand, therapeutical measures may be employed with reference to the danger of death, without regard to the nature or seat of the disease. A disease equal in all respects in different cases, may destroy the lives of some, while others recover, owing to the diversity which exists in different persons as regards the ability to sustain and overcome disease; and in the management of diseases, it is often the chief aim of the physician, in the language of Cullen, to obviate the tendency to death.

Prognostics are those circumstances on which a prognosis is based. They relate, of course, mainly to the symptoms of disease. Formerly, before the nature, seat, anatomical changes, etc., of different forms of disease were as well understood as now, all the circumstances connected with diseases were considered with direct and special reference to their significance as prognostics. The consideration of these is appropriate in treating of the principles of medicine, or general pathology; but it will suffice to consider them incidentally in connection with individual diseases. A few points which relate to the physiognomy or obvious appearances, and which render the prognosis unfavorable, may here be enumerated, by way of illustration.

Notable emaciation and pallor, existing in connection with any chronic affection, are unfavorable prognostics. Lividity of the prolabia and face, if persisting, generally denotes great danger. Great frequency and feebleness of the pulse, exclusive of diseases of the heart, and especially in acute diseases, point to a fatal termination. Great prostration is usually an alarming symptom. Spasmodic inspiration, if not dependent on pulmonary disease, precedes the development of coma, unless it be referable to hysteria. Coma, if it last more than one or two days, will be likely to end in death. Paralysis of the sphincters, leading to involuntary evacuations, and loss of the muscular power of deglutition, often denote impending dissolution. Impaired capability of feeling the presence of liquid in the air-passages, and inability to make the effort requisite for its removal by expectoration, are forerunners of the moribund state. A notable increase of the animal heat, as ascertained by the thermometer, if persisting, is to be reckoned among the prognostics denoting imminent danger. Finally, the characters pertaining to the physiognomy which constitutes the *Hypocratic countenance*, so called because they were described by the ancient father of medicine, denote the moribund state. These characters are, marked pallor with more or less lividity, pinching of the nostrils, sinking of the eyes, hollowness of the temples, coldness and transparency of the ears, dropping of the lower jaw, etc. The change in physiognomy in this state is so great, that persons are sometimes hardly recognizable. The features, to use a French expression, are decomposed, and a glance at the face often suffices to show that death is nigh at hand.

CHAPTER X.

PROPHYLAXIS—GENERAL THERAPEUTICS.

Experience the Basis of Therapeutical Knowledge—Two Sources of Experience; Analysis of recorded Cases with reference to the Duration or Termination of Diseases, and Observation of the Immediate Effects of Therapeutical Measures—Rational Inference as a Means of arriving at Principles of Therapeutics—Importance of Knowing the Intrinsic Tendencies of Diseases toward Recovery, or otherwise—Active Measures to be employed only when clearly indicated—The Expectant Plan of Treatment—Conservative Medicine—Importance of Hygienic Measures of Treatment—Modes of Dying resolvable into Apnœa and Asthenia—Classification of Therapeutical Measures, according to the Objects to be accomplished, into Prophylactic, Abortive, Curative, Palliative, Hygienic and Sustaining Measures.

THE prevention of disease is an object connected with pathological studies. It constitutes a division of medicine called prophylaxis. The name preventive medicine has of late been applied to it. It is one of the several aspects under which individual diseases are to be considered. As regards the beneficent fruits of knowledge, it holds a place not inferior to that of therapeutics. Many diseases are preventable by removing or obviating their causes; and it is with reference especially to this application, that the study of causes, or etiology, is of great practical importance. The knowledge already acquired of the causation of certain diseases, has proved of much value. A striking illustration of this is afforded by our present acquaintance with the poisonous effects of lead. It is only within late years that certain

diseases have been traced to the action of this poison. The diseases thus produced were doubtless of frequent occurrence before their causation was understood. The physician is now able sometimes to determine that diseases are thus produced, although he may not be able to ascertain in what manner lead has been introduced into the system; characters pertaining to the disease show that they have originated from this source. This statement is true of that form of paralysis called wrist-drop, and of the form of neuralgia known as saturnine colic.

The recognition of the germ-theory as affording the most rational explanation of certain of the special or specific causes of disease, has led to the employment, with great effect for the prevention of infectious diseases, of measures, the efficacy of which apparently depends on their agency in destroying the low forms of vegetable life. In this agency consists the efficiency of certain of the so-called disinfectants. The prevention of infectious diseases will be more and more efficient in proportion to the increase of knowledge of disease-producing organisms, together with the conditions under which they are multiplied. But without positive knowledge of the nature and origin of the causes of disease, we can, to a certain extent, secure exemption from their morbid effects by the knowledge which we possess of certain of the laws regulating their operation. Thus, the special cause of periodical fever, commonly known as malaria, may often be avoided by taking care to avoid exposure to the night-air and by sleeping in an upper story. Unknown special causes may be indirectly controlled, to a certain extent, by removing accessory or co-operating causes. In this way sanitary measures are efficient in protecting against epidemic and endemic diseases. Much has been accomplished in behalf of prophylaxis, but much remains to be accomplished. Sanitary reforms relating to ventilation, sewerage, cleanliness, etc., there is reason to believe, do very much towards the prevention of disease, and, hence, these are among the most important of the modes by which philanthropic efforts may be rendered useful to mankind. The prospect of diminishing the mortality from certain diseases relates more to prophylaxis than to therapeutics.

Therapeutics.

The division of medicine, devoted to the treatment of disease, is called *therapeutics*. The consideration of therapeutical measures, as regards the evidence of their usefulness, the rationale of their operation, the indications for their employment, etc., constitutes *general therapeutics*. The general principles of therapeutics are usually considered in connection with the principles of medicine or general pathology. The consideration of the treatment of individual diseases enters into special pathology or the practice of medicine, and constitutes *special therapeutics*. It will suffice here to offer a few remarks relating to general therapeutics, reserving the different therapeutical measures for consideration in connection with the treatment of individual diseases in the second part of this work.

It is needless to offer any remarks on the importance of therapeutics. The treatment of disease, next to prevention, is the great end of all studies relating to pathology, general and special. It is, however, the most difficult of all the branches of medicine for the teacher. It is so, not alone from uncertainty as regards the correctness of therapeutical principles, but because principles, undoubtedly correct in their general application, are to be greatly modified in adapting them to the varied circumstances pertaining to individual cases of disease. The same disease, under different circumstances, may claim, not only widely different modifications of treatment, but therapeutical measures directly opposite in character. There are abundant occasions

for citing illustrations of this fact in treating of individual diseases. It is impossible to formularize rules for the application of therapeutical measures. If this were possible, the practice of medicine would be a mechanical, not a rational, art. All that the teacher and author can hope to do is to present general principles together with the more important considerations involved in their application. And their successful application requires, not only knowledge, but reasoning powers, judgment, good sense and practical tact.

How are the facts and principles of therapeutics obtained? Mainly by experience. The question then arises, how are the results of experience, as regards the utility of therapeutical measures, obtained? There are two sources of experimental evidence in behalf of the utility of a particular method of treatment in any disease. One source of evidence relates to the termination and duration of the disease in a series of cases in which the method of treatment has been employed. The superiority of a method is shown by a larger number of recoveries and an average duration shorter in such a series than in other series of cases treated otherwise. This statistical investigation is open to certain fallacies. No two series of cases of a disease are in all particulars exactly alike. Cases differ in the degree of severity and extent of disease, in the constitutional condition of patients, in the existence or otherwise of complications, and in a great variety of circumstances pertaining to season, climate, age, habits, etc. The results of a comparison of different series of cases, in respect of termination and duration, are to be accepted as the basis of experience only on the ground that the differences in the different series mutually compensate for each other. Hence, the number of cases embraced in a series should be large, and the results of the comparison should be confirmed or corrected by being repeated with successive series of cases collected at different times and places and by different observers. Moreover, pains should be taken to group together cases resembling each other as closely as possible. Observing carefully all proper precautions, the results obtained by this kind of investigation are of great value, if deduced from data faithfully recorded by honest observers and competent diagnosticians. The memory is wholly inadequate for such an investigation. Moreover, recorded facts afford the only security against prejudice and bias. Unrecorded experience is by no means valueless, but it is of little relative value as compared with the results of the analysis of recorded data.

Another source of experimental evidence relates to the immediate effects of therapeutical measures irrespective of the termination or duration of diseases. The usefulness of remedial measures may be apparent from their immediate effects, although there may be no proof that the disease has been abridged, and in cases which end fatally. A method of treatment may be useful in a certain number of the cases in a series, although in the majority of cases it may be injurious. For example, let it be assumed, that in the larger number of cases of lobar pneumonitis, bloodletting does harm, it may nevertheless do good in a small number of cases; and, conversely, if it be assumed that this remedy is useful in the majority of cases, it may be pernicious in some cases. So with regard to other measures in other diseases.

It is thus evident that after the utility of particular therapeutical measures in certain diseases, as the rule, has been ascertained by means of a sufficient number of facts derived from the first source of experimental evidence, it is vastly important for the physician to exercise discrimination in the application of these measures to individual cases. And it is to be borne in mind, that, in the practice of medicine, the physician deals with cases of disease separately, not in aggregates. The general principles of therapeutics have a relation to individual cases of disease, not unlike that of the rates of life insurance to the liability to death of particular persons. It is easy to calculate the

probabilities of the duration of life in a large number of persons of a given age, and to determine exactly what it is worth to insure the lives of a large number, but no one thinks of applying to an insurance office to know how long he is to live!

Rational inference is a means of arriving at therapeutical principles. If, for example, it be known that a person has swallowed a corrosive poison, reason and common sense at once dictate the propriety of endeavoring either to expel it, or to neutralize it by an appropriate antidote. But, in such a case, experience must be resorted to to know whether either of these objects be practicable, which of the two is to be preferred, and the best means of effecting each. Analogical and *à priori* reasoning may lead to the employment of measures in the treatment of diseases, but the results of experience are necessary to establish their therapeutical value. Talent and genius may be shown in originating methods of cure, but the practical test of their efficacy is afforded by experience. It is true that false experience has abounded in medicine, but, if experience be open to fallacies, this is true to a far greater extent of theoretical or speculative reasoning. It is worthy of note that our knowledge of the most important remedies has been acquired wholly by experience, without any explanation of their *modus operandi*. Examples are, the salts of quinia as a remedy for periodical fever, mercury and iodine in certain forms of syphilis, etc.

The intrinsic tendency of a disease to recovery, or otherwise, is to be considered with reference to the value of therapeutical measures. Knowledge of the natural history of diseases is important as the true point of departure for therapeutics. Much has been acquired, within late years, in this branch of knowledge, but much remains to be acquired. Diseases which were formerly supposed to tend to a fatal result, if not treated by means of active remedies, are now know to end generally in recovery, if left alone. Examples are, acute pleuritis and uncomplicated lobar pneumonitis. The importance of increasing our knowledge of the natural history of diseases, by collecting cases which have pursued their course without active treatment, is to be kept in mind by those desirous of contributing to the advancement of therapeutics; and opportunities of accumulating such cases should not be neglected, always provided that the welfare of the patient be not compromised by withholding measures which there are good grounds for believing will prove useful.

It may be laid down as a golden rule in therapeutics that active measures of treatment are only to be employed in cases in which they seem to the physician to be clearly indicated. The severity of disease, and the danger of the patient, be they never so great, do not alone constitute grounds for the employment of active measures. If they be not useful, they will be likely to do harm. Therapeutical measures, in proportion to their power, are powerful for either good or harm, and must, therefore, be either indicated or contra-indicated. In the language of another, the physician "should be content with doing nothing when ignorant how to do good."

The term *expectant*, as applied to the treatment of disease, is often used, and its true sense is not always observed in its application. The treatment of a disease by expectation consists in watching carefully its progress, and meeting with appropriate measures unfavorable events as they arise. This plan is not inconsistent with the employment of active measures of treatment; but these are resorted to, not simply because the disease exists, but with reference to events connected with the disease. In this sense of the term, the treatment of a disease is expectant whenever the physician does not attempt to abridge or arrest it, but strives to aid in conducting it to a favorable termination.

The progress of medicine within late years, as regards therapeutics, is

characterized by the development of a principle which may be distinguished as *conservatism*. This term may be applied to medical as to surgical practice, and denotes an object which has not heretofore been sufficiently considered, namely, the avoidance of useless and injurious therapeutical measures. Conservative medicine does not interdict the use of the most potential of remedial agencies; but it enforces discrimination and circumspection in their use, recognizing fully their potency for evil as well as for good. The conservative physician is by no means a mere spectator of the progress of disease, but, in wielding the resources of therapeutics, he is careful to preserve the powers of life, following the injunction of Chomel not to treat disease, but patients affected with disease.[1]

The management of cases of disease involves not only the exercise of judgment in the employment, or otherwise, of therapeutic measures, but attention to hygienic regulations. And in a better appreciation of these, the practice of medicine at the present time offers a striking contrast with the past. It may perhaps safely be said that the greater success attending the management of diseases now, than heretofore, is due as much to improvements as regards diet, ventilation, etc., as to the more judicious use of remedial agencies.

In the treatment of diseases involving danger to life, the mode of dying is to be considered. It is always a useful inquiry at the bed-side, by what mode of dying will the case under treatment end fatally if the patient do not recover? The answer to this question will often furnish the indications for treatment, by means of which the danger may be forestalled; and here, it is plain, is the source of indications under circumstances in which it is the aim of the physician to "obviate the tendency to death." It suffices for all practical purposes to reduce the different modes of dying to two, namely, by *apnœa* and by *asthenia*.

Death by apnœa is produced by interruption of the function of respiration. The type of this mode of dying is furnished in cases of strangulation. Death by this mode occurs when produced by affections involving obstruction to the passage of air to the air-cells of the lungs, such as acute laryngitis, œdema of the glottis, foreign bodies in the air-passage, and capillary bronchitis. It occurs sometimes when a considerable portion of the pulmonary organs is rendered incompetent to receive air, as in pleuritis with large effusion, pneumonitis affecting both lungs, and acute tuberculosis. It also occurs when the respiratory movements are arrested by an affection of the medulla oblongata, involving the suspension of the reflux influence by which these movements are sustained. When death occurs from coma, the mode of dying is by apnœa. In this mode of dying, the embarrassment of respiration is out of proportion to the disturbance of the circulation, and, when death takes place purely by this mode, the action of the heart continues after the cessation of respiration.

Death by asthenia, on the other hand, is due to the failure of the circulation. The action of the heart may be suddenly arrested by paralysis from over-distension of the ventricles, by the pressure of blood from an aneurism opening into the pericardium, by pericardial effusion, and by the coagulation of blood within the cavities. But in all diseases which prove fatal by adynamia or exhaustion, the mode of dying is by asthenia, and, when death takes place purely by this mode, respiration continues for a greater or less period after the pulse has ceased to be appreciable at the wrist. Apnœa, however, is frequently combined with asthenia in producing death; the diminished muscular power renders the patient unable to prevent the accumulation of

[1] *Vide* "Essays on conservative medicine and kindred topics" by the author.

liquid in the air-passages, and the respiratory function also may be interfered with by congestion and œdema of the lungs due to exhaustion. So, also, asthenia is frequently combined with apnœa in fatal affections of the organs of respiration. In fact, in a large proportion of cases, the two modes of dying are combined, either the one or the other mode predominating.

With a view to reference in the second part of this work, a classification of measures of treatment, based on the general objects which the physician aims to accomplish in the management of individual diseases, will be convenient. These objects are embraced in the following classes:—

1. *Prophylactic or preventive measures.*—Vaccination is a preventive measure with respect to smallpox. Quinia, given to protect against intermittent fever, is a measure belonging to this class. Measures to eliminate excrementitious principles from the blood when their deficiency in the urine is ascertained, before the manifestations of uræmia take place, is an example. The ejection of poisons from the stomach, and the employment of antidotal remedies, belong in the same category.

These prophylactics apply to individual cases. A wider range of prophylactic measures takes in the destruction of the special causes of disease by disinfectants, the avoidance of exposure to these causes by removal or isolation, the observance of the laws of health as regards habits of life, etc., in short, everything belonging to Public and Private Hygiene. Preventive medicine, with this comprehensive scope of application, cannot be here considered. The prevention of particular diseases will, however, enter into their consideration in the part of this work devoted to the Practice of Medicine.

2. *Abortive measures.*—The measures in this class are those employed with a view to arrest the progress of a disease at the outset; to cut it short, or strangle it. Quinia given in large doses in intermittent fever is an abortive remedy. It is not easy to cite many examples of this class. The range in which abortive measures are effective, with our present knowledge, is small. Here is abundant room for further developments in therapeutics.

3. *Curative remedial measures.*—Those measures which abridge the duration of a disease, diminish its severity or danger, and, in general terms, modify or influence it in a favorable manner, may be distinguished as curative. Quinia is a curative remedy in the cases of periodical fever in which it is not abortive, and, also, in certain cases of neuralgia. Mercury and iodine are curative in cases of syphilis. Opium is a curative remedy in peritonitis, in spasmodic affections like colic, and in sporadic cholera. Many other examples of this class might be cited.

It is probable that remedies which are curative or abortive in certain diseases, act by destroying morbific germs or organisms; that is, the remedies are parasiticides. Assuming the correctness of the germ theory as applied to all infectious diseases, an important object in therapeutics is to ascertain what particular remedy is destructive to the germs or organisms peculiar to each of these diseases. Experience teaches that a remedy which arrests one infectious disease may have no effect upon another. For example, quinia arrests and prevents malarial fever, but has no prophylactic or curative influence upon relapsing fever; and so, in order to have controlling remedies for all infectious diseases, it may be necessary to discover as many different parasiticides as there are varieties of disease-producing organisms.

4. *Palliative measures.*—The measures belonging to this class are those which are employed with the object of relieving pain or suffering of any kind. These measures are directed, not to a disease *per se*, but to the symptoms or effects of a disease. But they may, to a greater or less extent, exert a curative influence. It is conceivable that relief of pain or suffering may conduce to the favorable termination of a disease in some cases.

5. *Sanitary or hygienic measures.*—The measures of this class relate to pure air, temperature, diet, cleanliness, moral influences, etc. Medicine has certainly derived as much advantage from this class, of late years, as from curative remedial measures. The improvements which have taken place in the management of diseases, as regards air, water, food, exercise, etc., are very great, but there is room for still further improvement.

6. *Sustaining or supporting measures.*—The measures of this class consist of tonic remedies, alcohol, and alimentation. The objects are to obviate a tendency to death by asthenia, and to forestall a degree of prostration dangerous to life. Sustaining measures are applicable to the treatment of all diseases which, if they prove fatal, will destroy life by asthenia; and they are indicated with an urgency corresponding to the danger of dying by this mode. These, together with palliative and hygienic measures, constitute the treatment of all diseases which cannot be arrested, and which are not amenable to curative measures. Not a few diseases will be found in this category.

The terms *analeptic* and *restorative* are applied to measures relating to diet, regimen, and remedies, when the object is, in general terms, to bring the system back to its normal condition. Supporting measures have reference more especially to acute diseases which threaten life. Analeptic measures are those called for when the general health is deteriorated, although there may be no disease which involves danger to life; when, in other words, the system is *below par*. They are often called *building-up* measures, and are indicated in a large majority of disorders and chronic ailments.

A very good division of therapeutical indications is into, 1st, the indications which relate to the removal or abatement of causes, or Causal indications; 2d, Symptomatic indications, or those having reference to the symptoms, irrespective of the nature and seat of the disease; and 3d, Pathological indications, that is, the indications derived from a knowledge of existing diseases considered with reference to their character, situation, and intrinsic tendencies.

Measures of treatment are sometimes classified and named from their action being in opposition to a particular morbid condition; thus, formerly, the term *antiphlogistics* was much in vogue, this name being applied to measures which were considered as opposed to inflammation. Of late, certain measures, the immediate effect of which is the diminution of the temperature of the body, are often distinguished by the name *antipyretic*. Quinia and some other remedies are called *antiperiodic*, from their efficacy in arresting affections which are characterized by intermittency; remedies which are antagonistic to the effects of syphilis are called *antisyphilitic*, etc. It is, however, an error to suppose that it is a governing principle in therapeutics to employ remedies or measures, the action of which upon the body in health is the opposite of the effects or manifestations of disease. This principle is expressed by the term *allopathy*, a term applied by Hahnemann to denote a therapeutical doctrine the reverse of *homœopathy*. Legitimate medicine recognizes no such restricted and exclusive dogma as these two terms alike denote; and, hence, the name allopathy is to be by no means accepted, but considered as a term of unmerited reproach.

An important precept in therapeutics is the observance of simplicity in prescribing remedies. As a rule, remedies differing in their effects, should not be given in combination or at the same time. Different remedies should be conjoined only when they co-operate for a common object, such, for example, as a cathartic or a diuretic operation. This precept is important, not only because different remedies are likely to conflict with each other, but because it is difficult to judge of their efficacy severally. To observe the separate effects of particular remedies in individual cases, is essential in order to obtain

that experience which will be useful to the same patient at other times, and in other cases of the same disease. The experience of the physician accustomed to prescribe together multifarious remedies, must, of necessity, be confused and uncertain. Moreover, complicated prescriptions are objectionable on the score of their tending to invest the practice of medicine with an unworthy mystery. These remarks, of course, do not apply to uniting with a curative remedy medicines designed to correct incidental effects which it is desirable to avoid, or to diminish the repulsiveness of a remedy, or to secure for it a better tolerance. These objects, in the combination of medicines, are important. Not the least conspicuous of the modern improvements in medical practice relates to the use of alkaloids and concentrated remedies, together with other contrivances to divest remedies of a nauseousness which was formerly, as a matter of course, associated with the idea of a drug.

In the popular mind the practice of medicine is too closely connected with the use of drugs. Not disparaging the value of these, it is desirable for the public to understand that the proper office of the physician is to observe cases of disease, and to either prescribe or withhold remedies according to the indications. To forbear medicinal interference is as important in some cases as is active treatment in other cases, and to exercise this forbearance often requires, on the part of the physician, much firmness, on account of not only the expectations, or, it may be, solicitations, on the part of patients and others, but of his own anxiety to render efficient services. It should be an object with medical men to endeavor to correct popular errors in regard to the use of drugs and other therapeutic measures.

A considerable share of medical practice consists in the treatment, not of the individual diseases which are to be taken up in the second part of this work, but of disturbances of health which have no well-defined places in medical nosology. These disturbances often proceed from the operation of morbid causes, intrinsic or extrinsic, which it should be the aim of the physician to ascertain, and the removal of which, if possible, is to be effected. The development of serious diseases may, doubtless, in this way frequently be prevented. In many cases, the knowledge and skill of the physician are called into requisition to determine that no serious or well-defined disease exists. It is by no means the sole office of the physician to treat diseases. To indicate the causes of disease, more especially the voluntary violations of the laws of health; to enjoin such a course of life as shall seem most likely to afford security against disease, and promote physical and mental vigor; to decide in cases of disease against the employment of active therapeutical measures,—these are duties not less important than the employment of potent remedies whenever the latter are required.

In the management of cases of disease, mental influences are often of not a little importance. The physician may in many cases effect much by judicious encouragement, and by stimulating the voluntary efforts of the patient. Hopefulness and a strong will are curative agencies which are frequently powerful auxiliaries to medicinal remedies, and they are sometimes more potent than drugs; on the other hand, despondency and a lack of resolution have a depressing effect which, in some cases, tells greatly against recovery. Certain disorders may be produced and prolonged indefinitely by mental causes, the removal of which is essential to a cure. Too much concentration of the attention on the functions of the body is a common source of disorder among persons who, from want of occupation, unfortunately become unduly engrossed with their physical condition; and, in such cases, to divert the mind from the body is an object not less important and difficult than, in other cases, to secure a proper degree of care for existing ailments. The ability to exert those mental influences which are suited to different cases, conduces, in

no small measure, to success in practice; and this ability requires, in addition to natural powers, knowledge of human character, and a tact which is acquired by experience. A cheerful mien, and manners calculated to inspire confidence, are by no means beneath the attention of the physician, but, on the contrary, they are to be cultivated as highly useful professional attainments. Medicine, in its practical aspect, involves knowledge, judgment, and skill, as regards, not only the employment of the several classes of the therapeutical measures which have been enumerated, but the mental influences suited to the circumstances peculiar to individual cases of disease.

The history of medicine shows many and great mutations in the prevailing doctrines of therapeutics at different periods. The medical practice of the present day in many respects is in striking contrast to that current a half century ago; and it is by no means improbable that a comparison with the present day at the end of the next half century, will reveal points of contrast not less striking. These mutations, so far from being a reproach, illustrate the progressive character of medicine. Therapeutical principles can never become unchangeably fixed until the utmost limits of attainable pathological knowledge are reached, and nothing further remains to be ascertained by experience. It would be absurd to claim for medicine this perfectibility; but continued improvement in the management of disease may be reasonably expected. Future improvement will doubtless embrace the addition of new remedies and measures of treatment, more extended and precise knowledge of those already in use, and the correction of errors which probably now, as heretofore, render sometimes the efforts of the physician not only inadequate but prejudicial.

The uniformity of the laws of disease at different periods and places has been already referred to. The bearing of this on the stability of therapeutics is obvious. So, also, with reference to the same application, it is important to assume that the system of man is not liable to alterations which render the operation of therapeutical agencies widely different at periods not far removed from each other. The opinion held by some that such alterations have occurred within the memory of those now living, does not rest on any solid basis. Admitting to the fullest extent diversities attributable to race, climate, occupation, hereditary influences, etc., these do not invalidate the statement that the human constitution remains essentially unchanged, as regards the application of established therapeutical principles. Were the truth otherwise, it would strike at the root of medical experience. If changes requiring a revolution in therapeutics were liable to occur with each successive generation, it is evident there could be no permanent principles of medical practice; the fruits of experience, in our day, which so many are striving to develop, would be not only useless, but an injury to those who are to come after us.

The medical student and practitioner should have a just appreciation of the relative agency of nature and art in the recovery from disease. It is customary and convenient to personify disease, speaking of it as of an enemy to be recognized, attacked, and, if possible, vanquished. Remedies and therapeutical methods are said to be curative, as if disease were overcome exclusively by them. The mind should not be deceived by these figurative expressions. In reality, recovery from disease is always effected by nature, that is, by the agency of processes inherent in the organism. All that art can do is to remove obstacles to the operation of natural processes, and to promote their favorable operation. Take as an example a remedy which is considered as specially curative, namely, quinia, in periodical fever; this remedy, strictly speaking, does not cure the disease, using the term cure in its conventional sense, but it removes something on which the continuance of

the disease depends. This something removed, nature effects the cure. As another example, opium does not cure peritonitis, but, by promoting rest of the inflamed part and tolerance of the disease, it affords aid to nature in effecting the cure. In like manner, all remedies and therapeutical measures exert their so-called curative effects in one or the other of these two ways. The expression *vis medicatrix naturæ*, which has been used from time immemorial, represents the agency of nature in the cure of disease. That the physician is the servant, not the master, of nature (medicus naturæ minister, non magister est), and that, using the term cure in its literal sense, he has the care of diseases, but nature effects the recovery (medicus curat sed natura sanat morbos), have long been recognized truths, as these old aphorisms prove. To these may be added an aphorism by a modern author, Prof. Gubler, "l'organisme se guérit lui-même."

Let it not be considered that, to attribute supreme agency to nature, is to disparage art. The triumphs of the latter are made none the less beneficent and brilliant by subordination to the former. The achievements of the human mind in every direction are dependent on circumstances and laws determined by a higher power.[1]

This chapter concludes the first part of this work, the part devoted to the Principles of Medicine or General Pathology. A succinct account of the changes belonging to morbid anatomy, and of the general pathology of the blood, has been presented, together with certain distinctions, definitions, and general considerations relating to etiology, symptomatology, diagnosis, prognosis, prophylaxis, and therapeutics. These subdivisions of the principles of medicine have been considered as fully as is deemed important by way of preparation for entering on the study of individual diseases. The latter will be considered in the remainder of the work, which is to be devoted to the Practice of Medicine, or Special Pathology.

[1] The relative agency of nature and art in recovery from disease is clearly and cogently set forth by Alexander Harvey, M.D., in his "First Lines of Therapeutics," 1879.

PART II.

PRACTICE OF MEDICINE, OR SPECIAL PATHOLOGY.

INTRODUCTION.

Of the different aspects under which Individual Diseases are to be considered in treating of the Practice of Medicine or Special Pathology—namely, Anatomical Characters, Clinical History, Pathological Character, Causation, Diagnosis, Prognosis, Prevention and Treatment—Sense of the Term Individual as applied to a Disease, and the several Grounds of Individuality—Varieties of a Disease—Definition of the Terms Acute, Subacute, and Chronic—Symptoms or Events incidental to Disease sometimes, for convenience, considered as Individual Diseases—Self-limited Duration of Certain Diseases—Nosology—Nosological Arrangement adopted in this Work.

THE *Practice of Medicine, or Special Pathology*, treats of individual diseases. In this department of medical study, individual diseases are considered under several different aspects. One of these aspects relates to the appreciable changes found after death. These changes belong to morbid anatomy. Some diseases are characterized by morbid appearances in the parts affected, and other diseases are not accompanied by any lesions which are appreciable. The latter are distinguished as *functional diseases*. The term *anatomical characters* of a disease expresses the changes, belonging to morbid anatomy, which occur in connection with that disease. This term will be adopted as the title, usually, of the first aspect under which diseases not functional will be considered.

Another aspect relates to the phenomena or events which compose the *clinical history* of a disease. Under this head will be embraced precursory or prodromic events, the symptoms which accompany the access and those which occur during the career of the disease under consideration, the order of their succession, the laws regulating the development and progress of the disease, etc. This will constitute the second of the different aspects under which individual diseases, severally, are to be considered.

A third aspect relates to the *pathological character* of a disease. This aspect embraces what is known of the nature and seat of the morbid conditions which constitute, or enter into, the disease under consideration.

A fourth aspect relates to *etiology*, or the *causation* of a disease. Under this head will be stated what is known of the cause or causes of each individual disease.

A fifth aspect relates to *diagnosis*, or the discrimination of diseases. The application of the methods of investigation which, by means of symptoms, laws, etc., enables the physician to recognize the disease under consideration, and to distinguish it from other diseases, will be considered under this head. Physical signs, whenever these are available in the diagnosis of a disease, will be embraced under this head.

A sixth aspect relates to *prognosis*. This aspect embraces the intrinsic tendencies of diseases as regards termination in death or recovery. The cir-

cumstances which denote, on the one hand, a favorable, and, on the other hand, an unfavorable, progress of diseases, will come under the head of the prognosis. And the consequences more or less remote, or sequels, may sometimes be conveniently embraced under this head.

A seventh aspect relates to the *treatment* and *prevention* of a disease. The consideration of the treatment of each disease will embrace the indications for therapeutic measures and the remedies which experience has shown to be useful in that disease. Hygienic measures also will enter into the consideration of treatment. Prophylactic measures of treatment will claim consideration in treating of different diseases, and the measures which remove or obviate the causes of disease, will often be found to be not less important than the judicious application of principles of therapeutics.

Before entering upon individual diseases, it may be well to inquire what is meant by this use of the term individual, and whence does a disease derive its individuality. An individual disease differs from other diseases sufficiently for it to be regarded as separate and distinct. The sense of the term individual, in this application, is analogous to that of species, in natural history. The individuality of a disease is established by distinctive features pertaining to its clinical history. These distinctive features may be derived exclusively from the seat of the disease. Thus, pleuritis and pericarditis are inflammatory diseases of a serous membrane, and have essentially the same pathological character; but the different anatomical relations of the pleura and pericardium furnish sufficient points of distinction to constitute each of these affections an individual disease. In other instances, distinctive features are derived from the processes belonging to disease. Inflammatory diseases, for example, differ essentially from those which are not inflammatory. Again, certain diseases derive each an essential distinction from its dependence exclusively on a special cause. It is sufficient to show that a disease is produced by a special cause to establish its claim to be regarded as an individual disease.

An individual disease is to be distinguished from individual cases of disease. An individual case of disease has a relation to an individual disease, like that of a particular man to the species *homo*. The study of individual cases of disease belongs to clinical medicine. Some individual diseases embrace several varieties. Empyema and pneumo-hydrothorax may be considered as varieties of pleuritis, both consisting in inflammation of the pleura, the former differing from ordinary pleuritis in the fact that the liquid contained in the cavity of the pleura is purulent, and the latter differing in the fact that air and liquid are contained in that cavity. The several types of intermittent fever, distinguished as tertian, quotidian, etc., are different varieties of one disease. In the progress of medicine, certain diseases have come to be considered as essentially distinct, which were formerly regarded as different varieties of one disease. This is true of all the eruptive fevers. It is probable that certain diseases now considered as individual will be hereafter found to be divisible into two or more.

Differences as regards severity and duration constitute a basis of the division of a disease into varieties. The same disease may be either *acute*, *subacute*, or *chronic*. A disease is acute when it has a certain degree of intensity and runs a rapid career. In general, an acute disease is of sufficient gravity to confine the patient to the bed. The subacute variety of a disease has less intensity, frequently not compelling the patient to keep the bed, and perhaps not preventing him from being about, or even pursuing his usual occupation. The chronic variety exists when a disease is subacute and has continued for a considerable period. Some diseases are never chronic. This term, for instance, is not applicable to typhus or typhoid fever. The division into varie-

ties, based upon the differences just named, is especially applicable to inflammatory diseases.

The list of individual diseases embraces some, recognized as such for the sake of convenience, which, in reality, are only effects or symptoms of diseases. Jaundice, for example, is an effect or symptom occurring in connection with different diseases. Dropsy is in the same category. It is, however, convenient to consider jaundice and the different forms of dropsy as if they were individual diseases. In fact, if we were better acquainted with the primary or elementary forms of disease, it would probably appear that not a few of the diseases now considered as individual, are only manifestations of morbid conditions at present occult—the latter constituting the true diseases.

A point of distinction among diseases, interesting and of much practical importance, relates to duration. Some diseases continue for a definite period, never exceeding certain limits in this regard. The duration of certain diseases is regulated by fixed laws; that is, they rarely end until after the lapse of a certain number of days, and never exceed a certain number of days in their continuance. The continued and eruptive fevers are examples of diseases, the duration of which has definite limits. Intermittent fever, on the other hand, has no fixed or definite duration, if its course be not interfered with. Diseases which tend intrinsically to end after a certain time, are distinguished as *self-limited.* The laws of different diseases with respect to self-limitation are often to be taken into account in the employment of therapeutical measures; and it is obvious that these laws are to be considered in estimating the amount of curative influence exerted by methods of treatment. One of the most striking and important of the characteristics of modern medicine is the knowledge which has been acquired of the self-limitation of different diseases. Facts have shown that even Pulmonary Phthisis, in some cases, ends in recovery from an intrinsic tendency thereto.

In treating of individual diseases, some classification of them is essential. The classification of diseases constitutes a division of medicine called *nosology.* The history of medicine furnishes many nosological systems, the relative merits of which it would be useless to discuss. Undoubtedly, a scientific mode of classifying diseases would be to arrange them after essential points of distinction relating to their pathological character. But, with our present knowledge of the pathological character of different diseases, to do this is impracticable. A nosological arrangement on this basis must be deferred for a future period, when pathology has advanced far beyond its condition at this time. The same remark is applicable to any arrangement based on differences as regards the causes of diseases. Our present knowledge of etiology is not sufficient to furnish the basis of a permanent nosology. Inasmuch as the chief object of a classification is convenience, the proper course to be pursued, evidently, is to adopt a provisional plan which will best subserve this object. And the most convenient classification, at the present time, is that which has of late years been adopted by the majority of authors and teachers. This consists in dividing diseases into, *first*, *general*, and, *second*, *local.* General diseases are those which involve more or less disturbance of the whole system, this disturbance not having been preceded by any known local affection, local affections, if they occur, being developed secondarily. To this class belong the essential fevers. Under the head of constitutional diseases, it is convenient to include some in which the local manifestations have no fixed seat, and sometimes differ in character. Rheumatism and gout are constitutional diseases, the chief manifestations consisting of local affections differently situated in different cases, and at different periods in the same case. The local affection, however, is, in each, essentially the same wherever seated. Syphilis is another constitutional disease manifesting itself in local affections which differ, not

only in situation, but in character. The want of fixedness or uniformity in the seat of local affections proceeding from constitutional disease, and their diversity in character in some instances, are the grounds for placing certain diseases in this class. A large proportion of the affections, nosologically considered as local, probably proceed from constitutional disease; but as the local affections are fixed and uniform, and our knowledge of the constitutional disease is, for the most part, inferential, it is more convenient to arrange them in the second division.

The second division, or local diseases, will embrace all which are not reckoned as general, or constitutional. The number of local diseases is far greater than that of the diseases embraced in the first division. It is necessary to arrange them into subdivisions. And the most convenient plan is to distribute them into groups corresponding to the distribution of the different organs of the body into physiological systems. According to this plan the different local diseases are subdivided as follows:—

1. Diseases affecting the respiratory system.
2. Diseases affecting the circulatory system.
3. Diseases affecting the hæmatopoietic system.
4. Diseases affecting the digestive or chylopoietic system.
5. Diseases affecting the nervous system.
6. Diseases affecting the genito-urinary system.

The foregoing arrangement of local diseases will be adopted, and they will be considered in sections corresponding to the groups just enumerated; afterward a section will be devoted to general diseases.

Of the diseases belonging to these several groups, those only will be considered which are medical, as distinguished from surgical. The surgical diseases are those which are either external or in accessible situations. Thus, diseases of the mouth, throat, and nasal passages, of the anus and rectum, of the urethra and bladder, of the eye and ear, and of the vagina and uterus, fall within the province of surgery. Diseases of the skin, being external, belong to surgery, notwithstanding they receive special attention from the physician perhaps oftener than from the surgeon. As an additional reason for not including them among the diseases to be considered in this work, there are many treatises devoted specially to their consideration.

SECTION FIRST.

DISEASES AFFECTING THE RESPIRATORY SYSTEM.

CHAPTER I.

ACUTE PLEURITIS.

Division of the Diseases affecting the Respiratory System into Inflammatory and Non-inflammatory—Acute Pleuritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis.

OF the diseases affecting the respiratory system, an obvious division is based on the existence, or otherwise, of inflammation. Inflammatory diseases are seated respectively in three important structures comprised in the organs of the respiratory apparatus, namely, the mucous membrane lining the air-passages, the serous membranes which invest the lungs, and the pulmonary parenchyma. Inflammation affecting the structures just named gives rise to pleuritis[1] or pleurisy, pneumonitis or pneumonia, and bronchitis. These will be treated of in the order in which they have just been enumerated. The first disease to be considered, namely, pleuritis, may exist as an acute and as a subacute or chronic affection, the inflammation being diffused over the affected membrane. These two varieties of the disease will claim separate consideration. Other varieties, to be considered separately, are empyema, pneumo-hydrothorax, and circumscribed pleuritis. It will be convenient to notice, in connection with these varieties of pleuritis, the dropsical affection known as hydrothorax.

Acute Pleuritis.

The pleura, anatomically, is essentially similar to other serous membranes. It is composed of white fibrous connective tissue, containing a network of elastic fibres. It is divided into two layers, namely, the visceral and the parietal. The free surfaces of these two layers are smooth, polished, and covered with a single layer of polygonal, flat, nucleated cells called epithelial cells, or better, according to recent nomenclature, endothelial cells. A slight serous transudation moistens these surfaces. A network of capillary bloodvessels, derived from larger vessels in the subserous connective tissue, is present in the pleural membrane. The pleura forms on each side a shut sac. Its cavity stands in direct communication with the lymphatic channels present in the pleural tissue.

Anatomical Characters of Acute Pleuritis.—The first noticeable appearance, could the inflamed part be seen during life, would doubtless be redness from hyperæmia of the vessels within and beneath the pleural membrane. Redness here, as in other situations, may diminish and disappear after death.

[1] With a view to uniformity as regards nomenclature, the terms pleuritis and pneumonitis are used instead of pleurisy and pneumonia.

It is supposed that, for a brief period after the commencement of inflammation, the membrane is abnormally dry from suppression of the transudation which moistens it in health. It loses its glistening appearance and soon becomes somewhat swollen and opaque from serous infiltration into its substance. Small extravasations of blood or ecchymoses are not infrequently present in the pleural tissue.

Very soon the surface of the pleura becomes covered, either in patches or continuously, with a delicate layer of fibrin, derived probably from coagulation in the exuded liquor sanguinis. This layer of fibrin increases in thickness. It is also called coagulable lymph and false membrane. Its presence is essential as a criterion of acute inflammation of the pleura. The quantity of fluid exudation in the pleural cavity does not at first usually exceed a few ounces, and in some cases never passes beyond this moderate limit; in other cases it gradually or rapidly increases, and may finally amount to several pints. It is not everywhere clear like the serum of the blood or a purely dropsical effusion. The upper portion is usually clear, if the body have not been much disturbed in opening the chest, but near the bottom it is turbid from the admixture of flocculi of coagulated fibrin or lymph. Serum and fibrin are not the only inflammatory products present, but there is always to be found in the pleural tissue, in the fibrinous membrane, and in the fluid in the pleural cavity, a varying number of leucocytes or pus-cells and of red blood-corpuscles. The red blood-corpuscles pass through the unruptured capillary walls by the process known as diapedesis, and the pus-cells are mostly, if not entirely, emigrated white blood-corpuscles. The presence of a very large number of red blood-corpuscles renders the exudation hemorrhagic, a condition observed especially in certain dyscrasiæ, such as scorbutus, and in tuberculous and cancerous pleuritis. Pus-cells, although always present in the exudation, are not in sufficient number in the form of pleuritis under consideration to give to it a purulent character. The exudation is essentially sero-fibrinous.

What part the endothelial cells take in the inflammatory process, is not well understood. According to some pathologists, they simply fall off and undergo regressive metamorphoses. Other observers maintain that they swell up, become granular, assume amœboid movements, and even proliferate, producing young cells resembling pus-cells. There is a similar discrepancy of opinion as to the rôle of the connective-tissue cells in the pleural tissue.

At a later period of the disease, the fibrinous exudation which covers the pleural surfaces, becomes denser, and is frequently disposed in the form of a series of layers. It may adhere with considerable tenacity to the pleural surface, and the opposing surfaces of the pleura are thereby agglutinated, when not separated by fluid. The pleural tissue itself is infiltrated with emigrated white blood-cells and with some red blood-corpuscles, and presents, in a certain degree, the characters of embryonic tissue.

The presence of serum and fibrin, in varying relative proportions, in other words, of a sero-fibrinous liquid, together with the addition of a comparatively small number of pus-cells, is characteristic of simple acute pleuritis. The liquid in the pleural cavity occupies space at the expense of the volume of the lung. As it accumulates, it compresses the lung, the latter occupying a space reduced in proportion to the amount of liquid. If the pleural surfaces be free from old adhesions, and not agglutinated by fibrin, the relative situations of the liquid and lung will vary according to the position of the body. If the patient be sitting or standing, the liquid gravitates to the bottom of the sac, and rises to a height proportionate to the quantity. If the patient be recumbent on the back, the liquid gravitates to the posterior part of the chest, and the lung will descend in front, more or less, in a direction toward the diaphragm. In like manner, if the patient lie on the face, the liquid

occupies the now depending anterior part of the chest, and the lung will descend behind. These changes in relative situation are frequently available in determining, by physical signs, the existence of liquid in the pleural cavity.

If the disease progress favorably, the liquid diminishes progressively, with variable rapidity in different cases, being absorbed by the lymphatics and bloodvessels. It diminishes often with considerable rapidity until it is reduced to a small or moderate quantity, and then the absorption takes place slowly—a clinical fact probably due to the increasing density of the liquid from the larger relative proportion of fibrin as the serosity lessens, and to the increased density of the fibrinous layers with which the pleural surfaces are coated. The absorption of the fibrin occupies a considerable period after all the liquid has been absorbed. In the mean time, the pleural surfaces, coming into contact over their entire area, are agglutinated by means of the intervening fibrin, and this exudation is replaced by a newly-developed adventitious tissue which unites by permanent adhesions the surfaces in apposition. It is to be noted that the union by means of the adventitious tissue is not mechanical, as when the surfaces are agglutinated by fibrin, but vital, that is, by an organized membrane. The adhesions may extend over the whole of the pleural surfaces, and then the serous cavity is obliterated, or they may be limited to certain portions, in the latter case constituting ligamentous bands. This true membranous tissue was formerly supposed to be organized fibrin or lymph, but this view of its production is at present abandoned. The fibrin becoming granular, disintegrates and is absorbed, and the same is probably true of most of the cells in the fibrinous and fluid exudation.

The new connective tissue takes its origin from the pleural tissue itself, and, as it appears, chiefly by the activity of the emigrated white blood-corpuscles, although the participation of the endothelial and connective tissue cells in its formation is not improbable. The pleural membrane, being thickened by infiltration with round cells and the growth of new bloodvessels, comes to resemble granulation-tissue. Whether the new bloodvessels are offshoots from the pre-existing capillaries, or whether they are formed independently of them, is not yet established. At first they have a wide lumen and embryonic walls. Villous projections grow out from the granulation tissue and may meet corresponding projections from the opposite side. The length of these projections is thought to depend upon the amount of fibrin or liquid which separates the pleural surfaces during their growth, for the production of new connective tissue is going on coincidently with the absorption of the inflammatory exudation. This new tissue, at first rich in cells and bloodvessels, is gradually transformed into firm, fibrous tissue. The round cells give rise to branching connective tissue cells; between the cells appear, either as a metamorphosis of their substance or developed in the intercellular substance, connective tissue fibres. The bloodvessels shrink, lose the embryonic character, and many of them become entirely obliterated. Thus are formed the thread-like or band-like adhesions between the pleural surfaces and the fibrous thickening in the pleural membrane itself.

The adhesions by means of organized tissue take place during convalescence. At first, they are weak and liable to be broken by active exercise, or in acts of coughing. Hemorrhage may in this way occur. They become stronger with time, so that when death occurs after the lapse of several weeks or months, the lung is detached and removed from the chest with considerable difficulty. After a time, all the lymph disappears, and nothing remains but the newly-produced tissue. It may be remarked, in passing, that after the serous cavity is thus abolished, there is no space for the effusion of liquid to constitute hydrothorax, and œdema of the lung may take its place under circumstances which give rise to dropsical effusion in the opposite side. A

case has come under my observation exemplifying this fact. It is also to be remarked that these adhesions, however extensive, occasion no appreciable disturbance of respiration. They are, in fact, innocuous, and perhaps confer exemption from recurrence of pleuritis on the same side. Nor do they give rise to any diagnostic physical signs.

The accumulation of liquid in acute pleuritis may take place in such quantity as to fill the cavity of the pleura, compressing the lung into a small solid mass. The compressed lung loses all the physical characters dependent on the presence of air in the pulmonary vesicles. It resembles a mass of flesh, and is therefore said to be *carnified*. The pulmonary structure, however, remains intact, and it is capable of being inflated, after death, nearly or quite to the same extent as if it had not undergone this compression. A similar expansion may take place during life, after the absorption of the liquid. So large an accumulation of liquid, however, occurs much oftener in chronic than in acute pleuritis.

In cases of acute pleuritis which pursue a favorable course, absorption of the liquid commences a few days after the accumulation has reached the maximum. Should the quantity remain stationary or the diminution take place very slowly, after the lapse of two or three weeks the disease has become chronic. The greater part of the liquid is sometimes absorbed, and vital adhesions take place between the larger portion of the pleuritic surfaces, leaving a circumscribed space in which a certain quantity of liquid may remain for an indefinite period. The disease then eventuates in a circumscribed chronic pleuritis.

The foregoing description of the anatomical characters of acute pleuritis relates to its occurrence as a primary disease so far as any other pulmonary affection is concerned. Occurring independently of any prior disease of the lung, the inflammation is general, that is, it extends over the greater part or the whole of the serous membrane. It is otherwise when pleuritis is consecutive to another pulmonary disease. Occurring, as it does almost constantly, as a complication of lobar pneumonitis and pulmonary tuberculosis, the inflammation is limited to a portion of the membrane; the pleuritis is circumscribed. Circumscribed pleuritis, developed thus as a secondary affection, is rarely accompanied by liquid effusion. It is distinguished from general pleuritis by this fact; the exudation of fibrin only occurs, and the pleuritis is said to be dry (pleuritis sicca). Primary or idiopathic pleuritis is seated in the left oftener than in the right side.

Clinical History.—The most convenient division of acute pleuritis into stages, is to consider as the first stage the period from the attack to the time when an appreciable quantity of liquid effusion has taken place; the second stage will extend to the time when the liquid begins sensibly to diminish, and the third stage will comprise the period occupied in the absorption of the liquid. The first stage, or the period anterior to an appreciable amount of liquid effusion, is usually of short duration. The physical signs may show the presence of liquid within a few hours from the date of the attack. The stage rarely extends beyond twenty-four hours. The second stage is of variable duration. The accumulation of liquid may go on with more or less rapidity. When the maximum amount is reached, the quantity may remain stationary for some time, or absorption may speedily begin. The liquid may diminish under the effect of treatment, and renewed effusion take place. The disease does not, of course, advance beyond the second stage in the cases in which it eventuates in chronic pleuritis. If a considerable quantity of liquid remain at the end of from three to four weeks, the disease is to be considered as having become chronic. In cases which pursue a favorable course, con-

siderable progress should be made in the removal of the liquid after this lapse of time. The duration of the third stage, or the stage of absorption, is quite variable. Generally some liquid remains when the general symptoms denote convalescence, and even after the patient has apparently recovered. The physical signs may show the presence of fibrin for some time after the date of convalescence. From what has been stated, it follows that the duration of the career of the disease is from two to four weeks.

The invasion is sudden, and often without premonition. In a certain proportion of cases, however, pain or soreness is felt for one, two, or three days before the development of acute inflammation. The development of acute inflammation is characterized by symptoms which sufficiently mark the date of its occurrence. It is sometimes ushered in by a well-pronounced chill, accompanied perhaps with rigors. Chill and rigors, however, are by no means so frequent, nor, as a rule, so marked as in cases of pneumonitis. Not infrequently chilly sensations and slight shiverings only are experienced.

Pain in the affected side attends the onset of acute inflammation in a large majority of cases. The pain is usually intense. It is sharp, cutting, or lancinating in character. It is felt especially in the act of inspiration; it increases during inspiration, often becoming so severe that the act is instinctively arrested before being completed. Coughing and sneezing occasion severe pain. The movements of the body are painful, but in a far less degree than the respiratory movements. The pain is referred to the middle and lower third of the affected side of the chest, and is often diffused over the anterior, the lateral, and sometimes the posterior portion. It is not, as a rule, circumscribed or limited to a small space. The morbid sensitiveness of the inflamed pleura seems to me adequate to account for the production of acute pain, as a result of the movements of the pleural surfaces upon each other, and the stretching of the membrane, without requiring the hypothesis that either intercostal neuralgia, or an affection of the costal muscles, is superadded to the inflammation. Pain, with the characters just described, is almost uniformly present in acute pleuritis, but cases occur in which it is not marked, and is even wanting, other symptoms showing the inflammation to be acute.

Pyrexia is coincident with the development of the inflammation. The pulse is increased in frequency, rarely, however, exceeding 100 per minute. The temperature of the surface is raised. The thermometer in the axilla shows more or less intensity of fever, but the rise rarely exceeds 102°. As a rule there is less pyrexia than in cases of pneumonitis. The usual concomitants of symptomatic fever, namely, thirst, anorexia, pain in the head and loins, restlessness, muscular weakness, etc., are more or less marked. The intensity of the fever, and of the general or constitutional disturbance, varies much in different cases of this, as of other inflammations. In rare instances the fever is intense, the temperature rising to 105° or higher, with a corresponding intensity of other constitutional symptoms (pleuritis acutissima). In most of these instances the pleuritis is of the suppurative variety or empyema.

A comparison of the two sides of the chest, as regards temperature, shows a slightly higher temperature on the affected side, the difference being a fraction over one degree.

Cough is usually present, but it is sometimes wanting. The pain in coughing leads instinctively to efforts to repress it, and this gives to the mode of coughing a character denoted by the term suppressed. The patient succeeds, to a certain extent, in these efforts. The expectoration is slight or wanting, and, when present, it consists of simple mucus. The exceptions to this rule are the cases in which the development of pleuritis is preceded by bronchitis. When these affections are associated, it is merely a coincidence; there is no tendency in either to give rise to the other.

The respirations are increased in frequency, but not greatly. Their increased frequency at this period is due to an arrest of the inspiration before it is completed, in consequence of pain. The patient instinctively multiplies the respiratory acts to compensate for the want of a full inspiration. As a rule, the patient in lying chooses a position on the healthy side, the weight of the body upon the affected side increasing the pain and soreness. This rule is by no means without exceptions. Not infrequently the decubitus is either dorsal or diagonal.

These symptoms constitute the clinical history of this disease during the first stage, or prior to effusion. They continue into the second stage, but, after a certain amount of effusion has taken place, they are materially modified. The pain is notably lessened, and may disappear except on forced breathing. The acts of coughing are less painful, and the efforts at suppression are less apparent. The pyrexia diminishes and may even cease during this stage. Other evidences of constitutional disturbance are less marked. The patient reports better, and may be able to sit up and perhaps walk about the room. The respirations are more or less frequent; their frequency now depends on the compression of the lung by liquid. Their frequency will be great, other things being equal, in proportion to the quantity of liquid and the rapidity of the effusion. If a considerable amount of liquid be rapidly effused, the respirations are rapid, the patient suffers from a painful sense of the want of breath, or dyspnœa, and may be obliged to maintain the sitting posture. If the quantity be not large, and the effusion have not taken place rapidly, the patient will not be likely to suffer from dyspnœa while remaining quiet; but exercise will cause panting and a sense of the want of breath. Even with the pleural sac distended with liquid, the only effect on the breathing may be an increase of the frequency of the acts to twenty-five or thirty per minute, without suffering so long as the patient remains quiet. The diminution or cessation of pain is due to the restrained movements of the pleural surfaces upon each other, in consequence of the presence of the liquid and fibrin, the latter perhaps agglutinating the portions of these surfaces which are in contact. The change as regards fever and other constitutional symptoms, proceeds, in part, from the removal of the conditions causing pain, and partly, because, after exudation has taken place, the disease is mitigated from an intrinsic tendency to decrease. The patient now, as a rule, prefers to lie upon the affected rather than the healthy side, as in this position he is able to expand more freely the opposite lung. To this rule, however, there are exceptions; and the decubitus in this stage, as in the first stage, is frequently either dorsal or diagonal.

During the stage of absorption, pain is either wanting or produced only by muscular efforts; fever has disappeared; cough diminishes or ceases; the respirations become less and less frequent, and are less hurried by exercise; the appetite and digestion return, and the normal condition of all the functions is gradually restored. During this stage the patient is convalescent; he is able to be out of doors, and, perhaps, to resume in part his usual avocation and habits. Convalescence is declared, and the symptoms, both general and local, may appear to denote that recovery has taken place while some liquid effusion still remains; the fibrin is not yet fully absorbed, and the formation of new tissue leading to permanent adhesions is going on. A sense of weakness in the affected side, together with some soreness or pain on unusual exertions, frequently continues for some time after the termination of the career of the disease.

In primary or idiopathic pleuritis, the inflammation, as already stated, is diffused over the pleural membrane; it is general, not circumscribed. If circumscribed, it is a complication of some other pulmonary affection, as a

rule. It will be seen hereafter that it occurs as a complication of pneumonitis and phthisis, but it is generally, under these circumstances, subacute. Primary pleuritis does not lead to pneumonitis, except that the air-cells in immediate proximity to the pleura are sometimes involved; nor does it involve any tendency to bronchitis. It is a unilateral disease, that is, it affects the pleura of one side only. The exceptions to this rule are so infrequent, that the disease, when bilateral, or double, may be presumed to be secondary to another pulmonary affection, generally tuberculosis. I have met with a case of double pleuritis, accompanied with a large effusion into both pleural cavities. Death took place by apnœa, in this case, and pleuritis was found to be consecutive to miliary tubercles in both lungs. Such cases are extremely rare.

Pathological Character.—The disease is an example of acute inflammation affecting a serous membrane, and may be regarded as a type of all acute serous inflammations. The general pathology of inflammation has been considered in the first part of this work, together with the local variations when different structures are inflamed. Pleuritis and other serous inflammations are characterized by fibrinous exudation as a constant event (*vide* page 37). This event, the accumulation of liquid in the closed cavity, and the development of connective tissue, are characteristics of these inflammations. The accumulation within the pleural cavity of a purulent liquid, is the anatomical feature of a variety of pleuritis to be considered under a distinct heading (empyema, pyothorax, suppurative pleuritis). The form of the disease under consideration may be distinguished as a serofibrinous pleuritis.

Causation.—Acute pleuritis may be produced traumatically by contusions, especially if accompanied with fracture of the ribs, and by penetrating wounds. It is remarkable, however, that severe injuries of the chest often occur without giving rise to general pleuritis. The disease is attributed, in certain cases, to the action of cold. This has so long been considered as a frequent source of a great number of diseases, that patients at once are led to refer an attack to some exposure, often, doubtless, when it had no causative agency, or, at most, acted only as an exciting cause. Still, it is probable that the disease sometimes originates in this way. In the larger proportion of the cases in which it is not traumatic, it is spontaneous, that is, it proceeds from an unknown internal cause. It occurs sufficiently often in persons affected with the diseases of the kidneys embraced under the name Bright's disease, to show a pathological connection; and in these cases it is probably referable to the accumulation of urinary principles in the blood. It is developed occasionally in connection with acute articular rheumatism. It is an occasional sequel or concomitant of scarlatina, measles, and continued fever. It enters into the history of scorbutus, pyæmia, and septicæmia.

The liability to the disease is not equal at all periods of life. It is rare in infancy. It is not uncommon in childhood. It occurs in youth and middle life much more frequently than in old age. It is as rare in old age as in infancy. The proportion of males over females, among cases of this disease, vastly preponderates. There do not appear to be any causative influences pertaining to constitution, season, climate, or locality. The acute variety of pleuritis is not of very frequent occurrence, the subacute or chronic variety being more frequently met with. It is less frequent than pneumonitis, and, in relative frequency, bears no comparison with acute bronchitis.

Diagnosis.—Although the symptoms which enter into the clinical history of acute pleuritis are sufficiently characteristic to point to the existence of the disease, they are not sufficient for the diagnosis in all cases. The character-

istic pain is not peculiar to the disease. The pain in some cases of intercostal neuralgia and pleurodynia is as strongly marked as in acute pleuritis; and these three affections were formerly often confounded in practice. Moreover, the pleuritic pain in some cases of pneumonitis is as intense as when the pleuritis is a primary disease, and the former disease has not infrequently been mistaken for the latter. On the other hand, acute pleuritis is liable to be overlooked in the cases in which pain is slight or wanting. More or less fever is present in acute pleuritis, but this symptom may accidentally be associated with intercostal neuralgia; it will be likely to be present in pleurodynia, and it exists, of course, in pneumonitis. The diagnosis is to be based on the physical signs, taken in connection with the symptoms. The latter are of importance, and, indeed, essential in determining whether the affection be acute or not. The differential diagnosis consists in discriminating between the disease under consideration and intercostal neuralgia, pleurodynia, and pneumonitis.

The diagnosis in the first stage, with the aid of physical signs, cannot always be made with positiveness. Examination of the chest by inspection will show restrained movements on the side to which the pain is referred, the movements on the opposite side being increased, while on percussion, no distinct disparity between the two sides may be found; and on auscultation, the murmur of respiration is more or less weakened on the affected side. These signs are due to the fact that the pain leads instinctively to a diminished use of the lung on the side affected, while the use of the other lung is increased. They are equally present when the pain is incident to the affections from which this disease is to be discriminated. A slight friction murmur may be discovered in this stage; if present, its diagnostic significance is important. It shows that pleuritis exists, and the discrimination then lies between pleuritis as a primary disease or as a complication of pneumonitis. To decide this point at once is not always easy. The diagnostic sign of pneumonitis, namely, the crepitant râle, if present, settles the question; but as this sign is by no means present uniformly in pneumonitis, its absence does not authorize the exclusion of that disease. The same remark is applicable to the characteristic expectoration of pneumonitis. It must be confessed that, in a certain number of cases, this differential diagnosis requires some delay. A friction murmur is heard in only a certain proportion of cases during the first stage, and, if absent, the signs belonging to the second stage are essential in order to render the diagnosis positive.

The signs belonging to the second stage are usually present without much delay. If the disease be idiopathic pleuritis, after the lapse of twelve or twenty-four hours, effusion will have taken place in sufficient quantity to be apparent. The signs now denoting the existence of the disease are those due to the effusion. The diagnosis is based upon these signs, in conjunction with the symptoms and history, and on the absence of the signs of pneumonitis.

The signs of effusion are obtained by percussion, auscultation, palpation, and inspection. On percussion, dulness or flatness is found at the base of the chest, extending upward in proportion to the quantity of liquid, the patient being in a sitting posture. By the finger which serves as a pleximeter, also, is perceived an increased sense of resistance on percussion. The upper limit of the dulness or flatness, the position of the body being vertical, is not on a continuous horizontal line extending over the posterior, lateral, anterior aspects of the chest. In most instances it is higher behind than in front. Prof. G. M. Garland has found that, on the posterior aspect, the effusion is represented by a curved line resembling the letter S.[1] Having ascertained on the anterior aspect of the affected side a point which divides the dulness

[1] *Vide* "Pneumono-Dynamics," 1878.

or flatness below from the resonance above while the patient is sitting, changing the position of the patient to recumbency on the back frequently induces a marked change in the dividing line between dulness or flatness and the resonance; the liquid gravitating to the posterior part of the chest, the lung descends in front and furnishes resonance for a greater or less distance below the point which was coincident with the level of the liquid while the patient was sitting. This latter test of the presence of liquid is not available in all cases. If the pleural surfaces above the level of the liquid be united by old adhesions, or agglutinated by fibrin, the liquid and lung will maintain the same relation in different positions of the body. The failure of this test, therefore, is not proof against the presence of liquid. The test, however, is available in a large majority of cases. The resonance over the lung above the level of the liquid, if the latter rise to a third, a half, or, perhaps, two-thirds the height of the chest, is increased, and acquires, in part, a tympanitic quality, constituting vesiculo-tympanitic resonance.

That this vesiculo-tympanitic resonance may be due to emphysema of the upper lobe of the lung, I have lately (1879) had an opportunity of demonstrating. A hospital case presented the signs of pleuritis with considerable effusion, the vesiculo-typanitic resonance above the liquid being marked. The patient unexpectedly and suddenly died, and the cause of death was found to be a large thrombus in the left ventricle, the cardiac walls having undergone fatty degeneration. The lower lobe of the lung on the affected side was condensed, and the upper lobe was considerably emphysematous.

On auscultation, the respiratory murmur is either suppressed or feebly appreciable below the level of the liquid. Above the liquid it is usually weak as compared with the murmur on the opposite side. If the lung be considerably reduced in volume by the amount of liquid, the respiratory sound becomes broncho-vesicular, and the vocal resonance is increased. If the liquid be sufficient to compress the lung into a solid mass, the latter furnishes the bronchial respiration. The bronchial respiration is heard over the site of the compressed lung. It is usually limited to that site, but, in a certain proportion of cases, it is diffused over the greater part or the whole of the affected side. The normal vocal resonance, as a rule, is either suppressed or diminished over that portion of the affected side which corresponds to the space occupied by the liquid; but if the accumulation of liquid be large, bronchophony may be produced either over the compressed lung, or the portion in contact with the liquid. The bronchophony has sometimes a tremulous or bleating character, and is then ægophony. If the chest be filled with liquid, bronchophony is sometimes diffused over the whole of the affected side.

Vocal fremitus is either arrested or diminished by effusion as a rule. From this fact is derived valuable evidence of the presence of liquid when the effusion is in the right pleural cavity, in consequence of the greater amount of fremitus over the right side in health. If the question be as to the presence of liquid in the right pleural cavity, and the fremitus be greater on the left than on the right side, the evidence of liquid is strong. There are some rare exceptions to the rule that the vocal resonance and fremitus are either diminished or suppressed over the space occupied by the effusion.

If the quantity of liquid be large enough to distend the pleural sac, the intercostal depressions may be diminished or destroyed at the inferior, anterior, and lateral portions of the chest. This constitutes valuable evidence of the presence of liquid.

Other and marked signs of effusion are present if the quantity of liquid be sufficient to dilate the chest. This occurs exceptionally in acute pleuritis. It occurs much oftener in the chronic variety of the disease, and the signs referred to will be noticed in connection with the diagnosis of the latter.

The physical signs not only lead to a positive diagnosis after the first stage, but they show the amount of liquid in the pleural sac, a point of importance with reference to treatment. By means of daily explorations, the physician may ascertain whether the effusion be increasing or diminishing, and the rate of either the increase or diminution. The information thus obtained is highly important as a guide in the employment of therapeutical measures. This information cannot be obtained from the symptoms. The signs, therefore, are essential, not only to the diagnosis, but to a proper knowledge of the progress of the disease.

After absorption, to a greater or less extent, of the liquid, the pleural surfaces coming into contact over a larger area, and roughened by fibrin which has now become dense and closely adherent, a friction murmur is frequently produced. This is sometimes so loud as to be heard by the patient. It may continue into convalescence, ceasing when the pleural surfaces have become united by means of newly-formed tissue. A friction murmur, however, by no means occurs invariably even at this stage of the disease.

The occasional occurrence of a pleural, cardiac friction sound in cases of pleuritis affecting the left side is to be borne in mind. The movements of the heart sometimes occasion a rubbing of pleural surfaces sufficiently to cause a sound which, having the cardiac rhythm and being heard when breathing is suspended, may seem to denote pericarditis. The sound is limited to the left border of the heart, and pericardial effusion is, of course, wanting. Pericarditis, when this sign is present, it must be confessed, is not easily at once excluded. An error of diagnosis, in this regard, is more likely to occur from the fact that this disease is not a very infrequent complication of pleuritis.

Prognosis.—The prognosis in cases of acute, idiopathic, simple pleuritis is always favorable, provided the disease be uncomplicated, and the constitution of the patient be not enfeebled. Without any therapeutical interference it would very rarely prove fatal. I have collected several cases in which the disease passed through its course favorably without any treatment. It may possibly prove fatal in consequence of a large amount of effusion occurring very rapidly, death taking place by apnœa produced, probably, by congestion of the lung on the unaffected side (collateral flexion) in addition to the loss of function of the lung on the affected side from compression by the liquid. I have known one instance in which the death of a hospital patient, suddenly and unexpectedly, seemed fairly attributable to the fact that the pleural sac was greatly distended with rapidly effused liquid. Developed as a sequel to other diseases, or in the course of a grave affection such as chronic Bright's disease, or in persons with broken constitutions, it may destroy life by asthenia. Acute pericarditis is sometimes developed simultaneously with, or during the progress of, pleuritis, and these associated diseases are apt to prove fatal. Their occasional coincidence is to be borne in mind, or the pericarditis in this connection, if not carefully sought for, will be likely to be overlooked. As already stated, the development of pneumonitis consecutive to pleuritis is not to be expected, nor is there much danger that an acute pleuritis, after its development, will eventuate in suppuration, constituting the variety of the disease called empyema. In short, the intrinsic tendency of the disease is to recovery, a fatal termination being due very rarely to the disease *per se*, but to extrinsic circumstances.

CHAPTER II.

ACUTE PLEURITIS—(Continued.)

Treatment of Acute Pleuritis—Measures indicated in the First Stage—General Considerations relating to Bloodletting in Acute Inflammations—The use of Opium in Acute Pleuritis and other Acute Inflammations—Measures indicated in the Second and Third Stages of Acute Pleuritis.

THE objects of treatment in acute pleuritis differ in its different stages, and the latter, therefore, claim, severally, distinct consideration with reference to therapeutic indications. The objects in the first stage are to arrest, if possible, the progress of the disease, to diminish its intensity if it be not arrested, to limit the amount of morbid products, and to relieve suffering; in other words, the treatment relates to the employment of abortive, curative, and palliative measures. The indications in the first stage of this disease are essentially the same as in the early period of most acute inflammations. The general principles which should govern the treatment in this stage, therefore, will be here considered, and simply referred to hereafter in connection with other diseases to which they are measurably applicable.

Owing to its brief duration, patients are frequently not seen until the first stage has passed. Can the disease be arrested at this stage if the opportunity offer and a positive diagnosis be made? Admitting that, formerly, physicians did sometimes succeed, as they believed, in cutting short the disease, it must be said, in answer to this question, that there are no known abortive means which can be relied upon. Bloodletting and other so-called antiphlogistic measures formerly employed for this object, have certainly not been successful in a sufficient number of cases to warrant their employment to an extent which will render them likely to do harm if they be not successful. Assuming that the disease goes on to the second stage, the question then is, what curative and palliative measures are to be employed? This question leads at once to the consideration of bloodletting.

A great change has taken place with respect to bloodletting in the treatment of acute inflammations. This measure was formerly thought to be highly important, and was rarely omitted. It is now considered by many as seldom, if ever, called for. The infrequent use of the lancet now, contrasted with its frequent use forty years ago, constitutes one of the most striking of the changes in the practice of medicine which have occurred during this period. It can hardly be doubted that this measure was formerly adopted too indiscriminately, and often employed too largely; but, the natural tendency being to pass from one extreme to another, the utility of bloodletting in certain cases, at the present time, is perhaps not sufficiently appreciated.

Experience and pathological reasoning combine to show that bloodletting does not exert a direct controlling effect upon an inflammatory disease. It may exert a powerful immediate effect as a palliative measure, but whatever curative power it may possess is exerted indirectly. Its therapeutic action, in general, consists in lessening the frequency and force of the heart's action, together with arterial tension and the intensity of pyrexia. In the early period of an acute inflammation accompanied by notable pyrexia and arterial tension, the abstraction of blood affords relief, and may contribute to a favorable progress of the disease. It should enter into the treatment of a

certain proportion of cases, provided other and more conservative means for the same ends were not available.

The evils of bloodletting arise from its spoliative effect upon the blood. It diminishes the red globules, and these, during the progress of an acute disease, are not readily reproduced. It induces, thus, the anæmic condition, and in this way impairs the vital powers. It will be likely to do harm, therefore, whenever it is important to economize the powers of life, and it may contribute to a fatal result in diseases, or cases of disease, which involve danger of death by asthenia.

The useful effects of bloodletting may frequently, if not generally, be obtained by other means which require less circumspection in their employment, because, if injudiciously resorted to, they are in a less degree hurtful. The mass of blood may be temporarily lessened by saline purgatives and diaphoretic remedies, conjoined with a restricted ingestion of food and liquids. Depletion is obtained in this way without impoverishment of the blood. The frequency and force of the heart's action may be affected by nauseant sedatives, such as tartar-emetic, ipecacuanha, etc., and by direct sedatives, namely, digitalis, aconite, and the veratrum viride. By antipyretic remedies and measures for the abstraction of heat, the pyrexia may be lessened without the expenditure of blood, and thus the evils of bloodletting avoided. The advantage of bloodletting consists mainly in the promptness of its operation. Several hours are required to secure results from the means employed in lieu of bloodletting, whereas the effects of the latter are produced in a few moments.

In accordance with these views, bloodletting is never indicated by the fact simply that acute inflammation exists; it is a measure directed, not to the disease *per se*, but to circumstances associated with the disease. The state of the circulation and other circumstances furnish the indications for the employment of this measure. It may be admissible if, with the development of inflammation, there exist notable pyrexia, the patient being robust and in good health when attacked, and the disease not involving danger of death by asthenia. The measure is admissible, under the conditions just stated, whenever the promptness with which its effects are obtained renders it desirable to adopt it in preference to other measures producing the same effects with more or less delay. *Per contra*, bloodletting is not admissible when the development of inflammation is not accompanied by notable pyrexia, when the patient was not in good health when attacked, when the constitution is feeble, and when the disease involves danger of death by asthenia. These rules of practice, while they accord to bloodletting therapeutic value, undoubtedly restrict its use within narrow limits.

Applying these rules to the disease under consideration, a patient in the first stage of acute pleuritis, robust, suffering from severe pain and dyspnœa, with high fever, the pulse moderately accelerated, and not weak, will derive immediate relief from the abstraction of from ten to sixteen ounces of blood. The loss of this quantity of blood, under such circumstances, in a disease like this, which does not tend to destroy life by asthenia, will give rise to no evil results, but will be likely to affect favorably the progress of the disease. On the other hand, a patient feeble, or anæmic, with a pulse more or less frequent, but denoting diminished power of the heart's action, should not be bled, notwithstanding the local symptoms would undoubtedly be thereby relieved. By impairing the vital powers, the loss of blood will do harm, and is not admissible under these circumstances merely as a palliative remedy. And, in the first case, if the local symptoms do not urgently call for immediate relief, other measures may be substituted for the bloodletting. It may be added that, aside from the immediate relief afforded in acute pleuritis by bloodletting, it

has been theoretically considered as preventing, in a measure, fibrinous exudation by lessening arterial tension.

Before leaving the consideration of bloodletting, several incidental points may be briefly noticed.

This measure is perhaps more applicable to the treatment of inflammation affecting the pulmonary organs than to the treatment of other inflammatory affections, in consequence of the relations of the former to the circulation. The free passage of the blood through the pulmonary circuit seems to be promoted, and the functional labor which the lungs have to perform is diminished by the abstraction of blood. At all events, relief of the pain and dyspnœa attendant on the early stage of acute inflammation of any of the pulmonary structures is more quickly and effectually procured by bloodletting than by other measures. Were it not for its ulterior effects, it would be invaluable as a palliative measure in pleuritis and other inflammatory affections within the chest.

In another mode the abstraction of blood may sometimes be peculiarly useful in affections of the lungs involving considerable or great obstruction to the passage of blood through the pulmonary circuit. This obstruction occasions an accumulation of blood within the cavities of the right side of the heart; hence, congestion of the systematic veins, giving rise, if sufficient in degree, to lividity or cyanosis. The accumulation of blood in the cavities of the right side of the heart, under these circumstances, weakens the force with which the ventricle and auricle contract, and paralysis of this portion of the heart from over-distension may follow. The formation of a heart-clot may be a consequence of this accumulation. In certain cases, bloodletting may be advisable with a view to diminish the accumulation of blood in the cavities of the right side of the heart; but it is to be employed for that end only when the contra-indications which have been mentioned are not present.

After bloodletting, the pulse sometimes appears to indicate increased power of the heart's action. The artery seems to strike against the finger with more force than before the abstraction of blood. Formerly practitioners were misled by this effect upon the pulse, and bloodletting was employed as a means of increasing the power of the heart's action. The sensation which the finger receives, in these cases, is delusive, and is caused by the quickness of the movements of the artery. This has been shown by the sphygmograph to depend on the diminished tension of the arteries following the abstraction of blood. It is to be borne in mind, in estimating the power of the heart's action by the sensible characters of the pulse, that the sense of resistance which is felt, and the amount of pressure required to compress the artery, are the evidences of strength.

To a certain extent the advantages of bloodletting, inclusive of the promptness of its operation, may be obtained by arresting temporarily or retarding the circulation in a part more or less remote from the seat of the inflammation. A ligature applied to one or more of the extremities will effect this object; so, also, will the removal of atmospheric pressure over a considerable space. There is reason to think that these measures as substitutes for bloodletting have not been sufficiently considered. It is probably owing to their effect in withdrawing temporarily a certain quantity of blood from the circulation, that dry cups and various so-called revulsive applications to the surface of the body, are of utility in the first stage of acute inflammation. A considerable number of dry cups applied to the chest constitute an efficient substitute for bloodletting, often affording promptly notable relief of pain and dyspnœa.

The evils of indiscriminate and excessive bloodletting are manifested by a larger rate of mortality in those diseases which tend to destroy life by asthenia, and it can hardly be doubted that the death-rate has been diminished by a much more sparing use of the lancet within late years. But the results

of injudicious bloodletting are manifested in cases which end in recovery, as well as in those which end fatally. These results consist in protracted convalescence and subsequent feebleness. The cases of different inflammations treated formerly by bloodletting, together with other measures entering into the so-called antiphlogistic method, and the cases now treated otherwise, present a striking contrast as regards the condition of patients during convalescence and after recovery.

The opinion held by some that diseases have undergone a notable change within the memory of those now living, has been already referred to.[1] They who hold this opinion suppose that bloodletting and other antiphlogistic measures are less appropriate now than formerly, in consequence of such a change. With a professional experience of over forty years, I do not hesitate to express a conviction that acute inflammations at the present day are essentially the same as they were as far back as the time just named, and that antiphlogistic measures were neither more nor less appropriate then than now.

In addition to general bloodletting, or the employment of venesection, much importance was formerly attached to the abstraction of blood by cups or leeches applied in the neighborhood of the inflamed part. Local bloodletting, in some cases, is more convenient than general; but, as far as the abstraction of blood is concerned, it is difficult to conceive that it is a matter of much importance from what part of the body or vascular system it is taken. Whether it be abstracted by means of cups, leeches, or the lancet, the benefit or injury will depend on the quantity withdrawn in a given period. Whatever advantage may accrue from the removal of a certain amount of blood by cups or leeches, over the extraction of the same amount by venesection, must be derived from the operation of the former as revulsive measures.

With these remarks, leaving the consideration of bloodletting, and reverting to the question concerning the curative and palliative measures to be employed in the first stage of acute pleuritis, we are led to the consideration of opium. And, with respect to this remedy, certain considerations may here be presented which will apply to the treatment of other inflammations.

A great change has taken place with respect to the use of opium in acute inflammations. It was formerly used with much reserve, under the apprehension that, acting as a stimulant, its influence upon the local disease must be unfavorable. It was regarded as antagonistical to the antiphlogistic plan of treatment. Clinical experience and sounder pathological views, however, have led to the knowledge of its great value in the treatment of inflammatory affections wherever situated. It is valuable, not alone as a palliative, but as a curative, remedy. Its palliative efficacy is, of course, intelligible; and we can also, to some extent, understand its curative influence. By relieving pain, it diminishes the determination of blood to the inflamed part, for pain is alone sufficient to occasion an increased afflux of blood to a part. This fact is illustrated by cases of neuralgia affecting a superficial nerve. Neuralgia of the supra-orbital nerve, for example, occasions a determination of blood to the conjunctiva, so that this membrane appears to be inflamed, and the congestion disappears directly the pain is relieved by a full opiate. Opium exerts also a curative influence by preventing or diminishing the constitutional disturbance which inflammations are apt to occasion; it places the system in a condition to tolerate better the local affection. The severity of an inflammatory disease depends much on the amount of constitutional disturbance which it occasions, and, with respect to the latter, different cases differ widely, although in each the degree and extent of the local affection be the same. Life is often destroyed, not in consequence of the injury done to the inflamed part,

[1] *Vide* page 117.

but because the vital powers are inadequate to bear the continuance of the disease. These considerations afford some insight into the utility of opium, especially when patients are able to take this remedy without inconvenience, there being, as is well known, a great difference among different persons in this regard. The evidence of the curative value of opium, of course, is derived from experience, and there is ample ground for the belief that, by its judicious use in acute inflammations, not only is their course divested of much of the suffering which would otherwise be experienced, but their intensity is lessened, and the danger of death diminished in those inflammations which tend to destroy life by asthenia. The immediate effect of this remedy is often very strikingly manifest in improvement as regards the local and general symptoms.

Considering now the use of opium in the first stage of acute pleuritis, after the abstraction of blood, if this be deemed advisable, or, after a saline purgative, if this be employed in lieu of bloodletting, it will generally be judicious to prescribe opium,[1] in some form, in doses sufficient to relieve pain, and place the system fairly under an anodyne influence. If the pain be severe, and the constitutional disturbance considerable, the use of opium need not be delayed for the operation of a purgative, but may be at once entered upon. This is, perhaps, the most judicious course in the majority of cases, a purgative being deferred until a distinct anodyne impression has been produced and maintained for some hours by opium. Conjoined with the use of opium, sedative remedies, addressed to the circulation, may be employed. These should not be pushed to the extent of producing disorder. If, for example, tartar-emetic be given, it should not be carried beyond the point of slight nausea; and the veratrum viride, if given, should occasion no appreciable effects beyond a reduction of the frequency of the heart's action. These remedies, it is to be borne in mind, are addressed, not to the disease *per se*, but to the symptomatic phenomena of the disease.

Aconite is a valuable sedative remedy in the early stage of this, as of other acute inflammations. The most effective mode of administration in order to secure promptly and fully its remedial effect, is that recommended by Ringer, namely, half a drop, or a drop, of the tincture to be given every ten minutes, or quarter of an hour, for two hours, and afterwards the dose repeated hourly. Smaller doses are to be given if the pulse become feeble, or there be much prostration.

A summary of the treatment of the first stage of acute pleuritis, then, will embrace bloodletting in some cases, the use of opium given sufficiently to relieve pain and tranquillize the system, a saline purgative, and remedies designed to act as sedatives upon the circulation. Blisters should not be applied in this stage. They occasion general disturbance more than enough to counterbalance any effect by way of revulsion. They add an inflammation of the skin to the existing inflammation of the pleura. A sinapism, turpentine stupes, or fomentations to the chest, will secure all the benefit of vesication without the annoyance and other evils of the latter. Moreover, a blister is an obstacle in the way of those examinations of the chest which are of importance as affording the only reliable information respecting the progress of the disease. The employment of cold in the form of the bath, the wet sheet, or sponging the body, and other antipyretic measures, are rarely called for in this disease, inasmuch as a high temperature (hyperpyrexia) is of exceptional occurrence. These measures, however, are indicated if the body heat rise to 104° or 105°, as occurs in the so-called pleuritis acutissima.

[1] The word opium is here used as a general term, including the alkaloids, morphia, and codeia.

The application of cold to the affected side, by means of the ice-bladder or by napkins dipped in ice-water and renewed every five minutes, is a safe and efficient measure for the relief of pain. Theoretically, the application of cold for a local effect may be considered to be useful by causing contraction of the vessels, and thereby lessening inflammatory exudation.

Preventing the respiratory movements of the chest on the affected side by means of long strips of adhesive plaster encircling this side and extending partially over the side not affected, affords notable relief of the lancinating pain felt in the acts of inspiration.

In the second stage, so long as the quantity of effusion is small and a further accumulation may be expected to take place, the indications belonging to the first stage may continue. If the pain be still acute and the fever have not abated, measures to relieve the former and lessen the latter are indicated. Bloodletting is rarely called for, but depletion by purgatives may be useful, not only by lessening fever, but by restraining the amount of effusion. Diaphoretic remedies are useful by contributing to the two ends just stated. Opium is indicated in proportion to the pain and constitutional disturbance, and sedative remedies addressed to the circulation may be employed.

These measures cease to be appropriate when considerable effusion of liquid has taken place, when pain is no longer a prominent symptom, and the pyrexia has either ceased or become much diminished. The object of treatment now is to promote absorption of the effused liquid. The means which may be employed for this object are, hydragogue purgatives, diuretics, blisters, and the use of certain remedies which have been supposed to act directly as sorbefacients.

Hydragogue purgatives act most promptly and efficiently. The more active hydragogues, which are drastic in their operation, should be given circumspectly, and generally need not be employed. Reference is had to such remedies as elaterium and gamboge. The saline purgatives, such as the bitartrate of potassa, either alone or in combination with jalap (pulvis purgans), the citrate or the sulphate of magnesia, are to be preferred as sufficiently effective and less severe. These will sometimes effect a rapid decrease of the liquid.

Diuretics are sometimes equally but less rapidly effective. They effect the object with less perturbation, and are less debilitating. The union of two or more diuretic remedies is more likely to prove effective than a single remedy of this class. Half an ounce of the infusion of digitalis, freshly made, given three or four times daily, and either the bitartrate or the acetate of potassa, given in addition, form a combination which is often efficient.

Restriction in the amount of fluids ingested is an important point with reference to absorption. The elimination of water by the bowels or kidneys is of little avail if the patient be allowed to take as much into the system as is eliminated. The quantity should be as small as is compatible with comfort.

Blisters, in this stage of the disease, doubtless contribute to the object under consideration. If other means be effective, however, they may be dispensed with. Their interference with examinations of the chest is a matter of considerable consequence, and the annoyance which they frequently occasion is not an inconsiderable objection. If employed, small blisters successively applied in different situations, removed as soon as vesication commences, the vesicated surfaces being allowed to dry up rapidly, accomplish all the good to be effected in this way, with the smallest amount of inconvenience both to the physician and patient.

Remedies which have been supposed to act as sorbefacients are mercury

and iodine. Mercury I have long ceased to employ in this disease. Of doubtful efficacy, the annoyance and other evils incident to mercurialization render it objectionable. The efficacy of iodine is, perhaps, equally doubtful, but it is not open to similar objections. It may be given internally, or applied externally in the form of either the ointment or tincture.

It is an important injunction not to continue perturbatory measures with a view to promote absorption too long, nor too push their use too far. The decrease of effusion, after it has reached a certain point, is apt to go on slowly, for reasons already stated. Whenever this point is reached, cathartics and diuretics should be discontinued, or employed with great moderation, else they will be likely to do harm, rather than good, by weakening the patient. And if, at any time, these measures appear to impair the general condition, the propriety of continuing them is doubtful. A leading object in the second stage of the disease is to maintain the constitutional strength. For this object the diet should be nutritious; tonic remedies are useful, and a little wine or spirit may be allowed. These measures should constitute the treatment after those designed to promote absorption have been sufficiently carried out, and should take the place of the latter whenever there is evidence of the strength giving way.

It is very rarely the case that this disease tends to a fatal ending by asthenia. Should such a tendency be manifested by the symptoms, namely, frequency and feebleness of the pulse, muscular prostration, etc., the measures which constitute the supporting treatment are of course indicated. These measures, which form the most important part of the treatment of the diseases involving danger by asthenia, consist of alcoholics, nutritious alimentation, and tonic remedies. They will be noticed more fully in connection with diseases in the treatment of which they are oftener called for (*vide* treatment of Pneumonitis, Chap. IV.).

A fatal result in acute pleuritis may be due to rapid and excessive effusion of liquid, as already stated. If the liquid accumulate sufficiently to endanger life, it should be at once withdrawn from the chest by aspiration. This measure is much more frequently indicated in chronic pleuritis, and will be considered in connection with the latter variety of the disease.

The measures which have reference to the promotion of absorption may continue to be indicated in the third stage; that is, for a certain period during the progress of absorption. When these measures have been carried to a sufficient extent, and the amount of liquid is considerably reduced, the patient is to be considered as convalescent. During convalescence the chief object is the re-establishment of the health of the patient. This is to be done by tonic remedies, a nutritious diet, and other hygienic means. Solid food, embracing a fair proportion of meat, may be allowed whenever taken with relish and digested. Alimentation is important; and if the appetite be small and the digestion weak, remedies to improve both are indicated. No apprehension need be felt that a diet as nutritious as can be taken without inconvenience will do any harm; on the contrary, the more nutritious the food which can be taken and digested, the more rapid the convalescence. Wine or spirit, or beer, in small quantities, taken with meals, will expedite recovery. Going out of doors and gentle exercise are to be encouraged. The patient will gain more rapidly as regards appetite, digestion, and strength, if not confined too long within doors; and with proper precautions, no risk of harm is incurred. The removal of the liquid which remains, the absorption of fibrin, and the development of new tissue leading to adhesions, will go on rapidly in proportion to the rapidity with which improvement in the general condition takes place.

In the foregoing account of the treatment of simple acute pleuritis, it is assumed that, exclusive of a small number of cases in which this disease destroys life either by asthenia or apnœa, its course is toward convalescence, without becoming chronic. This is the rule, to which there are exceptions. If the disease become chronic, the measures of treatment indicated are those which will be considered in connection with chronic pleuritis.

The prevention of acute pleuritis hardly claims consideration. The abrupt and rapid development of the disease precludes the employment of prophylactic measures, and there are no premonitions which warrant our anticipation of its occurrence.

Marked dulness on percussion over the affected side, especially at the inferior portion, continues for some time after the effusion has disappeared, the symptoms, general and local, denoting recovery, and the vesicular murmur of respiration being heard over the whole of the affected side. This shows that fibrin remains to be absorbed, but it need occasion no apprehensions. After the effusion has disappeared, as shown by vesicular breathing and vocal resonance extending to the base of the chest, considerable dulness remains and generally continues for several weeks.

CHAPTER III.

VARIETIES OF PLEURITIS.

Chronic Pleuritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Prognosis—Treatment. Thoracentesis. Suppurative Pleuritis, or Empyema—Diagnosis—Prognosis—Treatment. Pleuritis with Pneumothorax—Anatomical Characters—Clinical History—Diagnosis—Prognosis—Treatment. Pneumothorax. Circumscribed Pleuritis. Hydrothorax.

OF the varieties of pleuritis, the first to be considered is the simple or ordinary chronic form of the disease. Other varieties are suppurative pleuritis, or empyema, and pleuritis with pneumothorax. Circumscribed pleuritis will claim some consideration. This chapter will be devoted to these affections, including a brief account of pneumothorax without pleuritis, and of hydrothorax.

Chronic Pleuritis.

Anatomical Characters.—The anatomical characters in simple chronic or sero-fibrinous pleuritis are essentially the same as in the acute form. The pleural cavity contains serum and fibrin in variable relative proportions, but, as a rule, the quantity of fibrin is less, and the accumulation of liquid greater, than in acute pleuritis. Effusion frequently takes place to such an extent that the affected side is more or less dilated. The lung is then compressed into a small solid mass usually situated at the upper and posterior part; the thoracic walls are expanded in every direction; the intercostal spaces are pushed out to a level with the ribs or even beyond this level, and show no depression with the act of inspiration; the diaphragm may be depressed, pushing downward the abdominal organs situated in proximity to it, namely,

the stomach, spleen, and liver; the lateral pressure may be sufficient to move the heart from its normal situation, and, if the effusion be in the left side, the heart may be carried quite into the space belonging to the right side of the chest.

The dilatation decreases as absorption of the liquid takes place, and contraction of the affected side succeeds. The latter arises from the fact that the compressed lung does not readily resume its former volume when the pressure of the liquid is removed, in consequence of the layers of fibrin with which it is more or less invested, and, sometimes, because pleuritic adhesions have already taken place. Other things being equal, the extent of contraction is in proportion to the amount of the previous dilatation and its duration. Usually the dimensions of the affected side in every direction are lessened, the shoulder is lowered, and lateral spinal curvature is apt to ensue. In some cases in which the lung expands to a certain point and becomes fixed by permanent adhesions at that point, the removal of the liquid below leads to a deep depression; the chest presents an appearance as if the lower ribs had been crushed inward. The contraction succeeding a large effusion is generally permanent. It becomes less marked after several months or years, in some cases, and, if the patient be young, it may, in the progress of time, nearly disappear. In a patient who had chronic pleuritis with very large effusion, at the age of 17 years, followed by great contraction, I found, ten years afterward, the two sides presenting only a slight disparity. The formation of new connective tissue in the shape of fibrous thickening of the pleural membrane, and of bands of adhesion between the pleural surfaces, is more extensive after chronic pleuritis than after the acute form.

Clinical History.—Chronic pleuritis, in the great majority of cases, is a subacute affection from the first. Occasionally it follows the acute form of the disease. The chronic is a more frequent affection than the acute, a fact which shows that the latter does not usually precede the former, as has been stated by some authors. Of thirty-five recorded cases which I analyzed with reference to this point, many years ago, the inflammation was subacute from the first in twenty-nine. The left side is affected oftener than the right, as in acute pleuritis. Of forty-two cases, the left side was affected in twenty-three. Of seventy-eight cases analyzed by Blakison, the left side was affected in fifty-eight.

This variety of pleuritis is often developed imperceptibly, and, as far as the symptoms are concerned, it may be one of the most insidious and latent of diseases. It is often overlooked by those who do not employ the physical methods of examination. Its development is not, as in the vast majority of cases of acute pleuritis, characterized by pain. Pain is often either wanting or so slight as scarcely to attract attention. In some cases, however, the pain is moderate or considerable, but falling much short of that intensity which belongs to the acute affection. Tenderness over the chest is slight or moderate, and may be wanting.

Cough and expectoration are frequently wanting, and are rarely prominent symptoms. The cough, if present, is dry, short, hacking, and the matter of expectoration consists of mucus, transparent or slightly opaque. If there be considerable expectoration, and the matter expectorated be muco-purulent, either bronchitis coexists, or the pleuritis is associated with phthisis.

The frequency of the respirations is increased, assuming the pleuritis to be accompanied by a large effusion of liquid. The increase, however, may be moderate while the patient is at rest, but it becomes marked on exercise. Deficiency of breath is also shown by inability to speak with a sustained expiration, the speech being interrupted at short intervals for a fresh inspiration.

Dyspnœa is rarely present except on exercise. Here, as in acute pleuritis, the embarrassment of breathing depends much on the rapidity with which the effusion takes place. The suppression of the respiratory function of an entire lung, in this affection, if it be slowly induced, does not usually occasion lividity of the face or prolabia.

The pulse is generally more or less accelerated, ranging from 80 to 120 per minute. It is small and compressible. There is, however, considerable variation in different cases as regards these characters of the pulse. The surface of the body frequently presents more or less capillary congestion. Sweating is apt to occur, especially during the night, and may be profuse without having been preceded by a chill or febrile movement. Irregular, slight chills, however, are not unusual, leading sometimes to the error of supposing the disease to be malarial.

The appetite is sometimes notably impaired, but in other cases it is preserved, and the digestion continues good. Diarrhœa occurs in some cases. Generally, the countenance is pallid, denoting anæmia, but this is not true of all cases; a healthy aspect is sometimes maintained. Emaciation is not usually marked, except when the disease is associated with phthisis. The strength is often retained in a remarkable degree. Patients usually do not take to the bed, and they may be able to be up and out of doors, even with one side of the chest filled with liquid. I have known repeatedly persons in this condition to continue pursuits which required active muscular exertion.

This sketch of the symptomatology applies, of course, to cases of chronic pleuritis not associated with other affections furnishing symptoms which are combined with those belonging to the disease under consideration. It may be associated with phthisis, but not so frequently as is stated by some writers. Indeed, in my experience, the latter disease has coexisted in a small proportion of cases. Its coexistence will be likely to render cough more prominent, and give rise to a more or less abundant expectoration. Emaciation and muscular feebleness are also more marked. Pericarditis coexists in a small proportion of cases. With this complication, the circulation is more disturbed, there is more suffering from dyspnœa, and the symptoms in general denote greater gravity of disease. The affection may be developed in the course of either acute or chronic disease of the kidneys; under these circumstances, general dropsy may be present, emaciation and feebleness are greater, and the tendency to asthenia is more apparent. In like manner, other affections which may be associated, modify and add to the symptoms pertaining to the pleuritic inflammation.

The duration is variable, but the career rarely ends under several weeks, and generally it extends over several months. As regards stages, when acute pleuritis has not preceded, cases do not come under observation until more or less effusion has taken place, and, it may be, not until the pleural sac is filled with liquid. It suffices to consider the career of the disease as consisting of two stages, one embracing the period during which the liquid either is accumulating or remains stationary, and the other embracing the period during which absorption of the liquid is going on. After absorption has made a certain amount of progress, the patient may be regarded as convalescent.

Pathological Character.—Simple chronic sero-fibrinous pleuritis is a subacute inflammation differing from the acute form of the disease only in a lesser degree of the inflammatory condition. The inflammation has no special character, but is of a low grade of intensity, with a tendency to continuance for an indefinite period.

Causation.—Chronic pleuritis may be produced traumatically. It may sometimes be due to cold. It occurs occasionally during the course of affections of kidneys. In a large majority of cases, it proceeds from internal causes which are not understood, and it is then said to be spontaneous. In a small proportion of cases the chronic follows the acute disease. In much the larger proportion the inflammation is from the first subacute.

An important point of inquiry relates to its pathological relations to phthisis. According to some authors, it is generally consecutive to, and dependent upon, a phthisical affection. There has been no evidence of this in a large majority of the cases which have come under my observation. Of forty-two cases analyzed several years ago, the evidence of coexisting phthisis was present in only three; and of a large number of cases which I have since observed, I am sure that the two affections have been associated in but a small proportion. As, however, the occurrence of pleuritic effusion retards and contributes to the arrest of the progress of phthisis, the association of the two affections may sometimes exist without being apparent.

Chronic, as well as acute, pleuritis occurs rarely in infancy. It is not of infrequent occurrence in childhood and early life, but it is most frequent between puberty and middle life. It is of rare occurrence in the aged.

Prognosis.—Simple chronic pleuritis, not associated with phthisis, nor complicated with any serious affection, and occurring in a healthy subject, tends to recovery. A fatal result may take place in consequence of a rapid and large accumulation of liquid, but instances of this are exceedingly rare. If death occur, it is generally from associated affections or complications.

Recovery takes place leaving the affected side more or less contracted; and sometimes the contraction is so marked as, in connection with the lateral curvature of the spine which it occasions, to produce a considerable and permanent deformity. In general, however, the contraction which follows is attended with little or no inconvenience, and is not observed unless the chest be denuded, and the two sides compared.

A permanent dislocation of the heart to the right side of the sternum is sometimes an effect of the removal of a large collection of liquid from the right pleural sac; and, in some cases of pleuritis with large effusion in the left side, the heart, which was dislocated by the lateral pressure of the liquid, is found on the right side of the sternum after recovery from the pleuritis, adhesions having taken place which prevent it from returning to the left side after the liquid is removed.

Phthisis becomes manifest, sooner or later after recovery, in a certain proportion of cases. In some of the cases in which this disease appears to be a sequel, it may have existed prior to the pleuritis, and have undergone arrest. The proportion of cases in which phthisis follows is not sufficiently large to show a predisposition to this disease derived from the pleuritis. The opinion, frequently and perhaps commonly entertained, that chronic pleuritis, when it does not supervene on a phthisical affection, predisposes strongly to the occurrence of the latter, I believe to be incorrect. This belief is based on my own experience. It is sustained by statistics communicated many years since by Blakiston.[1] Of fifty-three cases observed by that author, the patients remaining under observation for several years after recovery, not one became affected with pulmonary tuberculosis. This result is striking, for it might be expected that, out of so large a number of cases of any disease occurring, as does pleuritis, for the most part at an early age, a certain proportion would be likely,

[1] Practical Observations on Certain Diseases of the Chest, etc. American edition. Blanchard & Lea, 1848.

in the course of several years, to become phthisical. In estimating the influence of this or any disease in determining the subsequent development of phthisis, the liability to the latter, irrespective of antecedent affections, is of course to be taken into account.

The idea that chronic pleuritis affecting the right side of the chest denotes phthisis, has been disproved by statistics reported by Bowditch.[1]

The mortality from chronic pleuritis, even without regard to associated affections and complications, is not great. The rate of mortality probably does not exceed that which, several years ago, I deduced from my recorded cases, namely, 17 per cent.

Recovery is understood to imply the removal, by absorption, of the effusion. The disease, however, may terminate in another way, leaving no local symptoms, and the patient regaining good health. This consists in the affected side of the chest remaining permanently filled with liquid. The following case, illustrative of this termination, came under my observation in the Charity Hospital of New Orleans in 1861 :—

The patient, a man aged about 45, stated that he had been ill and confined to the bed for four days, having previously been in good health. In answer to inquiries suggested by the marks of cupping on the left side, he stated that he had had pleurisy several years before. The left side was dilated, everywhere flat on percussion, and the respiratory murmur suppressed. Death occurred on the third day after his admission, and my notes do not contain data showing the probable cause of death The man presented a robust appearance, and declared that he was quite well when seized with illness four days before his admission. His habits were intemperate.

On examination of the chest after death, the left pleural sac was found to be so resisting that it was removed entire, and brought to the college. The sac was then opened with some difficulty, and a large amount of turbid liquid, estimated to be two gallons, removed. After the liquid had escaped, the pleural sac was sufficiently rigid to retain the shape which it had before being opened. A calcified fibrous tissue, from one-eighth to one-quarter of an inch in thickness, lined the entire pleura. The parietal portion of the membrane could in some places be stripped from this calcified tissue. Calcareous matter was abundantly deposited in the latter. The lung was compressed into a solid, small mass, which resisted efforts at insufflation.

Another case, illustrative of a similar permanency of effusion, came under my observation in private practice. A lawyer, aged about 30, had an attack of pleuritis, which confined him for some time to the bed, nine years before my first examination in 1861. Five years afterward he was in excellent health, being entirely free from any pulmonary symptoms except deficiency of breath on exercise. Flatness on percussion existed over the whole of the left side, with suppression of respiratory sound and vocal resonance, except at the summit where bronchial respiration and bronchophony existed. These signs were considered as denoting liquid in sufficient quantity to fill the pleural sac and compress the lung into a solid mass. The patient stated that he had been repeatedly examined since the attack of pleuritis nine years before, and there had been no change in the condition of the chest since his apparent recovery from that disease.

Diagnosis.—Owing to the latency of chronic pleuritis, as regards the subjective symptoms, in many cases, the existence of intra-thoracic disease is often overlooked by those who do not employ physical exploration. Of the cases which have come under my observation, in not a few the patients

[1] Bowditch, American Journal of the Medical Sciences, January, 1863.

have been supposed to have either dyspepsia, irregular malarial fever, hepatic trouble, or some ailment not connected with the chest. If the symptoms point to the existence of intra-thoracic disease, patients are often supposed to be phthisical, and the cough, deficiency of breath, night perspirations, etc., rationally favor such a conclusion. A positive diagnosis can hardly be made without the aid of physical signs.

The signs on which, taken in connection with the history and symptoms, the diagnosis may be based, are those denoting pleuritic effusion. The signs of effusion are the same in chronic, as in acute, pleuritis, and need not be again stated; but in chronic, more frequently than in acute, pleuritis, the accumulation of liquid is so large as to occasion more or less dilatation of the affected side, and then are superadded signs obtained by inspection and palpation, notice of which was deferred in treating of the acute disease.

Dilatation of the affected side by liquid is apparent to the eye, and may be ascertained by mensuration, either with graduated tape or callipers. The intercostal spaces are pushed out to a level with the ribs, and may be bulging. The side is motionless, or nearly so, in the acts of respiration, the movements of the opposite side being exaggerated. By applying the fingers within the intercostal spaces and applying peripheral and diametrical percussion, a sense of fluctuation is sometimes obtained. The heart is moved from its normal situation, as ascertained either by palpation or auscultation. If the effusion be in the left side, the apex-beat and the maximum intensity of the heart-sounds is on the right side of the sternum; and they are carried toward the left lateral portion of the chest if the effusion be in the right side. The diaphragm is depressed, pushing downward the abdominal organs in contact with it. The addition of these signs renders the diagnosis of pleuritic effusion still more complete and positive than the signs which denote the presence of liquid without dilatation.

The presence of liquid is demonstrated by the introduction of a small exploring trocar. A hypodermic syringe, the needle being sufficiently strong to obviate danger of its being broken off and remaining in the chest, answers for the exploratory puncture; or a small aspirating needle may be used. This should be resorted to in all cases, both of acute and of the different varieties of chronic pleuritis, in order to ascertain the character, as well as the presence, of liquid. With, as well as without, this exploration, there is one liability to error in diagnosis, namely, carcinomatous or sarcomatous infiltration of an entire lung may cause an enlargement of its volume, and, a certain amount of pleuritic effusion coexisting, the signs may seem to denote simply chronic pleuritis. An exploratory puncture demonstrates the presence of liquid. The diagnosis can only be settled by aspiration. Removing the liquid, the affected side remains enlarged; the needle or trocar even passes into a solid mass, as shown by its remaining fixed; that is, the point not movable while in the chest.

A sanguinolent effusion, if scorbutus be excluded, renders the coexistence of phthisis probable.

During the stage of absorption, the signs show the progressive diminution of liquid until the quantity is no longer sufficient to occasion dilatation, and, from this point, the continued decrease in quantity is ascertained as in acute pleuritis. The contraction of the affected side which follows chronic pleuritis is more marked than that succeeding the acute affection.

TREATMENT.—The main objects of treatment in simple chronic pleuritis are twofold, namely, *First*, to effect the removal of the effused liquid; and, *second*, to develop and sustain the powers of the system. For the first object, the measures which may be employed are the same as in the second and the

third stage of acute pleuritis, consisting of the milder hydragogues, diuretics, small blisters applied in succession over different portions of the affected side, and the use of iodine internally and externally. Bloodletting, general or local, is never indicated in chronic pleuritis.

In pursuing measures with reference to the first object, the second is not to be overlooked nor neglected. Cases are often injudiciously treated in consequence of the attention being too much engrossed with the measures to promote absorption; these measures will do harm if continued too long or pushed too far. After a certain amount of effect has been produced, if these measures cease to be further effective, they should be discontinued, at least for a time; nor should they be persisted in if they fail to have any effect. Harm is produced by their injudicious employment, in proportion as they debilitate.

The second object calls for tonic remedies, nutritious alimentation, the moderate use of alcoholic stimulants, and gentle exercise out of doors. These measures are always important, and they are pre-eminently so if, from associated affections, complications, or the general condition of the patient, the powers of the system be notably lowered. I have repeatedly seen a marked change for the better occur at once, followed by progressive improvement in all respects, on the discontinuance of measures having reference to the absorption of liquid, and the substitution of measures addressed to the system. Hygienic measures, namely, nutritious diet and exercise in the open air, under proper restrictions, are especially important.

A mode of effecting the first object, namely, the removal of the liquid, requires distinct consideration. Reference is now had to the operation of *paracentesis* or *thoracentesis*. The propriety of puncturing the chest when the accumulation of liquid is sufficient to place the patient in imminent danger, is unquestionable. But it is a question whether it be not advisable to puncture, although the patient be not in great distress or danger. It is clearly an object to get rid of the liquid, and the point is whether it be better to resort to the direct mode, that is, puncture and withdraw it, or to endeavor to effect the object indirectly by purgatives, diuretics, etc.

Formerly this operation was performed only as a *dernier ressort*, when little was to be expected from any measure. It was deferred as long as possible, sometimes on account of doubt as to the diagnosis, and because the perforation and introduction of air were supposed to involve danger of an increase of the inflammation. A considerable opening was necessary in order to give free exit to the liquid, and it was difficult to prevent air from entering the pleural cavity. Objection to the operation on the score of diagnosis is now removed by our present knowledge of physical signs. Moreover, the operation was divested of all severity, and the liability to the introduction of air provided against, by the application of suction in 1850. The introduction of air, aside from the entrance of organisms giving rise to putrefactive changes, is objectionable, because its presence is an obstacle to the full expansion of the lung after the liquid is removed, and with the air enter germs which occasion putrefactive and suppurative processes. Its introduction is prevented by the employment of a suction force in withdrawing the liquid. The operation is rendered trivial because, with suction, a small exploring trocar suffices to make the puncture which causes very little pain and closes directly the canula is removed.

The credit of the introduction of the practice of withdrawing the liquid through a small canula by means of suction, or, as it is now called, aspiration, is due to Bowditch. He operated in this way 250 times on 154 persons in the course of twenty years. In no instance was any permanent injury referable to the operation. It was in some cases repeated several times during the progress of the disease. In a considerable proportion of cases recovery

appeared to be attributable to the operation. Immediate and great relief was obtained in cases which ultimately proved fatal. Bowditch has been led by his experience to operate in all cases in which the quantity of liquid induces either permanent or occasional dyspnœa of a severe character, and in all cases in which the pleural cavity is filled, if, after a reasonable amount of treatment otherwise, the liquid do not diminish.

My own experience in the practice of the operation has been considerable, and I can testify in behalf of its innocuousness, the relief which it affords, and its value as a means of rescuing patients from a condition of imminent danger to life. And the conclusions of Bowditch, as just stated, are not only sustained by his large experience, and, at the present time, by the experience of many others, but they are consonant with common sense. If by an operation trivial with respect to pain or any evil effects, and easily performed, the effusion may be withdrawn at pleasure, this mode is certainly to be preferred to measures which are indirect, not very reliable, requiring considerable time, and producing more or less disturbance of the system and debility. An important advantage of the operation is, the liquid being removed before the lung has been subjected to long pressure, and has become adherent by dense layers of fibrin, or, perhaps, organized tissue, the expansion takes place more fully, and is followed by less deformity of the chest from contraction of the affected side. It is a noteworthy fact that, directly after the operation, the temperature declines and may fall to the normal standard.

Thoracentesis by means of a small trocar, with the aid of suction, the puncture made at a convenient point either behind, laterally, or in front, is admissible whenever the pleural cavity remains filled with liquid after a brief trial of the measures designed to promote absorption; and the operation should not be delayed whenever the accumulation of liquid is sufficient to involve danger or distressing dyspnœa.

For many years, in place of the suction-pump employed by Bowditch, I have used a simpler apparatus, namely, a small trocar and a canula fitted to screw upon the flexible suction-tube of Davidson's syringe. The canula should be provided with a stopcock. The trocar and canula being introduced into the chest, the trocar is withdrawn and the canula attached to the syringe; the liquid is then removed by means of the expansion of the India-rubber bulb after its compression with the hand. I have used this apparatus in many cases with satisfactory results. It has also been used with success by many others. After a certain quantity of liquid has been withdrawn, the patient often is seized with cough, and experiences a distressing sense of constriction in the chest. These symptoms probably arise from the atmospheric pressure upon the thoracic wall and from the disruption of the pleural surfaces, united by fibrin, by the expansion of the compressed lung. They may also be, in part, due to the suction force exerted laterally upon the lung of the healthy side. They may be delayed, and sometimes avoided, by withdrawing the liquid very slowly, thus allowing time for the expansion of the compressed lung, and the gradual accommodation of the parts to fill the vacuum occasioned by the removal of the liquid. When these symptoms occur, the further removal of liquid should be postponed for another operation. As regards the quantity removed at one operation, much will be gained by following the injunction to withdraw the liquid slowly, especially when the patient begins to cough and complain of constriction. The advantage of my apparatus over the suction-pump, is its greater simplicity, the ease with which it is managed, and a less liability to get out of order. More recently an instrument for aspiration, or aspirator, as it is called, constructed on a different plan, was introduced by Dieulafoy. The peculiarity of Dieulafoy's aspirator consists in first producing a vacuum in a glass receiver, and then opening a communication between

the latter and a canula or hollow needle introduced into the chest. A fuller description of the instrument is as follows: A glass cylinder is fixed upon a stand in an upright position; at the lower part there are two tubes, provided with stopcocks, one connected with a flexible tube attached to the canula or needle, and the other connected with a tube through which the contents of the cylinder are discharged. By means of a piston, with a rack and pinion movement, the air is withdrawn from the cylinder, after which the stopcock attached to the tube connected with the canula inserted into the chest is turned, and the liquid flows from the pleural cavity into the cylinder. After the cylinder is filled, its contents are expelled through the other tube, by turning the stopcock and reversing the rack and pinion movement. The apparatus provides effectually against the introduction of air into the chest; but this is sufficiently provided for in the other instruments used for aspiration. The suction force operates steadily, and a very small trocar or needle for puncturing the chest suffices. The cylinder being of glass, its contents are at once seen. The objections to the instrument are, first, that, being somewhat complicated, it is apt to get out of order; and, second, it is expensive as compared with the suction-pump, and especially with that devised by me. A little appendage has been added to the canula to be attached to Davidson's syringe, so that it may be in an instant connected with the latter. It is easy to secure more expansive force than is obtained by the ordinary syringe used for enemata, by having an instrument made especially for aspiration, with a larger and thicker India-rubber bulb.

A much simpler instrument than the aspirator of Dieulafoy, on the same principle, is a glass bottle from which, by an arrangement for that purpose, the air is withdrawn by means of a small syringe, and the communication with the canula within the chest then opened through a tube connecting the latter with the bottle. This kind of aspirator is just as efficient as the more costly one of Dieulafoy.

Dieulafoy's aspirators are provided with small trocars and hollow needles. The latter should never be used in aspirating the chest. The sharp needle-points are liable to tear the lung, with which it may come in contact, after a certain quantity of liquid has been withdrawn, giving rise to pneumothorax.

Failure in aspiration may be caused by the trocar carrying before it a portion of false membrane which prevents the liquid from being reached. With a view to obviate this difficulty, the trocar should be pushed with a certain degree of quickness and force into the chest. Another difficulty is the plugging of the end of the canula with floating pieces of fibrin. This obstruction may generally be removed by forcing some of the fluid back again through the canula into the chest.

Instances have been reported of grave symptoms and even death resulting from aspiration. Without discussing here the rationale of these effects of the operation, it may be stated that the risk of their occurrence is almost *nil*, if the fluid be withdrawn slowly, and aspiration be suspended directly cough or dyspnœa is produced. But even if this statement be not admitted, the risk is too small to constitute a serious objection to the measure if it be indicated. I may add that during the past fifteen years aspiration has been practised almost weekly in the wards of Bellevue Hospital, and I have not heard of a single instance in which any serious consequences have resulted from it. Only one instance has come within my cognizance in private practice. In this instance an alarming dyspnœa followed the removal of a large quantity of pus. This effect was temporary, and the case ended in recovery. It is probable that the effect in that instance was attributable to a too rapid withdrawal of the liquid. I had previously withdrawn a large quantity of pus in this case without any unpleasant symptoms.

Empyema, Pyothorax. Suppurative Pleuritis.

These names denote a variety of pleuritis characterized by the accumulation, in the pleural cavity, of a purulent liquid. The accumulation of pus is a feature sufficiently distinctive and important to serve as a ground for constituting this a variety of pleuritis. The term empyema only expresses the existence of pus, without indicating its situation. Pyothorax is a better name, but this does not express the existence of pleuritic inflammation. Suppurative pleuritis is a simple title suggested as more fully expressive of the affection.

Suppurative pleuritis may be either acute or subacute at the beginning, but it becomes chronic. It is therefore a variety of both acute and chronic pleuritis. The symptoms attending its development are essentially the same as in simple or ordinary pleuritis, either acute or chronic. There are no distinctive points pertaining to the symptomatology, and it is not necessary, therefore, to consider under a distinct head its clinical history. The anatomical characters, too, are essentially the same as in simple or ordinary pleuritis, excepting that, in the latter, the effused liquid is sero-fibrinous, whereas, in the variety under consideration, the liquid contained in the cavity of the pleura is pus.

The pathological character of suppurative pleuritis is inflammation, acute or subacute, resulting in suppuration. The production in abundance of pus cells, or the emigration of leucocytes, takes place at the outset. In other words, the accumulation of pus is not an accidental effect, nor does it depend on the duration of the inflammation. The inflammation, in cases of suppurative pleuritis, generally tends at once or speedily to suppuration. On the other hand, in cases of simple or ordinary pleuritis, the disease may continue for months and even years without eventuating in the accumulation of pus. The affection is rarely at first simple and subsequently suppurative pleuritis, but it is a distinct variety of pleuritis from the beginning. This statement, although not in accordance with what is stated by most medical writers, is sustained by my own clinical experience.

As regards causation, it may be produced traumatically; and it occurs spontaneously, the internal causative agencies in the latter case being, with our existing knowledge, neither more nor less comprehensible than when the inflammation is of the simple or ordinary kind. Why pleuritic inflammation in one case should lead to a collection of quarts or even gallons of pus, and, in another case, continue indefinitely without suppuration, we are unable to explain.

Diagnosis.—The signs as well as symptoms in suppurative pleuritis, are not distinctive of this variety. They represent the presence of more or less liquid in the pleural cavity, and they are essentially the same when the liquid is purulent as when it is sero-fibrinous. The point of inquiry, in regard of diagnosis, is, whether there are any means of determining that the liquid is purulent. This is an important point with reference to prognosis and treatment. The occurrence of chills, more fever, hectic paroxysms, etc., are not reliable in this differential diagnosis. As a rule, however, the axillary temperature is higher than in simple pleuritis. The symptoms and signs, in fact, exclusive of spontaneous perforation of the thoracic walls, will hardly warrant a positive diagnosis. But the purulent character of the liquid may be inferred with considerable confidence if the quantity progressively continue to increase notwithstanding the employment of measures to promote absorption. A serous effusion is generally either diminished or retarded by the use of hydragogues, diuretics, etc.; but these measures are not likely to exert any influence upon a purulent liquid.

A positive diagnosis, however, may be easily made by an exploratory puncture. A small trocar, or the needle attached to a hypodermic syringe, may be introduced into the chest, and a little of the liquid withdrawn; the gross and microscopical characters of the specimen thus obtained will at once settle the question. This procedure is warrantable as a means of diagnosis in view of the bearing on the prognosis and treatment. Indeed, the operation is so slight as to be in no wise objectionable.

Spontaneous perforation of the walls of the chest occurs, after a time, in cases of suppurative pleuritis. When this occurs, before ulceration of the integument ensues, a soft fluctuating tumor makes its appearance over or near the point of perforation. The appearance of such a tumor, developed rapidly without having been preceded by inflammation exterior to the thoracic walls, is at once significant of this variety of pleuritis. The size of the tumor may be observed to vary with forcible acts of inspiration and expiration. The action of the heart upon the liquid within the chest may communicate a pulsation to the tumor, and this may at first lead to a suspicion of aneurism; but an examination of the chest, by furnishing the evidence of the pleural sac being filled with liquid, will show the character of the affection. If the tumor be not opened, inflammation of the integument from distension, and ulceration supervene, and the pus makes its escape from the tumor and the pleural cavity. "Paracentesis from necessity," as it is called, has then taken place. This result is almost exclusively due to suppurative pleuritis, but I have known an instance in which spontaneous perforation took place when the liquid was not purulent.

In a smaller proportion of cases a spontaneous evacuation occurs in another direction. Perforation of the lung takes place, and the pus finds its way into the air-passages. The occurrence of this event is marked by a sudden and copious purulent expectoration. This expectoration continues for an indefinite period. With rare exceptions, air enters the pleural cavity, and the disease is converted into pneumo-pyothorax which will presently be considered under a separate heading. Perforation successively of both the walls of the chest and of the lung sometimes occurs.

Prognosis.—Suppurative inflammation of the pleura is a more serious disease than simple pleuritis, whether acute or chronic. Inasmuch as the pus cannot be removed by absorption, but must be evacuated either spontaneously or by puncture, the condition is analogous to that of a large abscess which, after opening, continues to discharge through a fistulous orifice. After the purulent contents of the pleural cavity are evacuated, the membrane continues to furnish pus, and thus the discharge continues indefinitely. Emaciation, debility, hectic paroxysms, etc., result from long-continued suppuration; and death takes place by slow asthenia. An unfavorable termination may be due, as in certain cases of simple pleuritis, to the coexistence of phthisis, pericarditis, or some other serious affection. In the case of a patient ten years of age which came under my observation, sudden death followed perforation of the lung, the discharge of pus taking place rapidly and causing suffocation by filling the bronchial tubes.

Recovery from suppurative pleuritis, however, is by no means infrequent, and may reasonably be hoped for if the patient have a good constitution, and the affection be uncomplicated. The purulent discharge continues for weeks, months, and perhaps years, but progressively diminishes; pleuritic adhesions take place, the affection becoming more and more circumscribed, until, at length, they become universal, and the recovery is completed, leaving the affected side considerably or greatly contracted.

TREATMENT.—In the treatment of suppurative pleuritis, no reliance is to be placed on measures to cause absorption of the purulent liquid. If the pleural cavity contain pus in considerable quantity, it will not be absorbed; but, if life be sufficiently prolonged, and thoracentesis be not resorted to, it will, sooner or later, make its way either into the air-passages or through the thoracic walls. Hydragogues, diuretics, blisters, etc., will not only prove unavailing, but they do harm by impairing the powers of the system. Thoracentesis should be performed as soon as the purulent character of the liquid is ascertained. Aspiration may be employed and repeated, but, in the majority of cases, owing to the reaccumulation of pus, this mode of performing thoracentesis will prove unsatisfactory. An opening should then be made at the bottom of the pleural sac, allowing the pus to escape freely. Air will of course pass into the chest, and, since this is unavoidable, its ingress and egress should be unobstructed. A small orifice, not sufficient for the free escape of the pus, and allowing air to be pent up within the pleural cavity, is injudicious. Having made a free opening, allowing all the pus to escape, the orifice should be kept open by the introduction of an oakum tent. This is preferable to the insertion of a drainage-tube which is a foreign body within the pleural cavity and therefore objectionable. The pleural cavity should be daily cleaned by the injection of tepid water, to which a very small quantity of carbolic acid (not more than one per cent.), is added. For the injection, a double-tubed catheter and Davidson's syringe suffice. If this be not done, the pus within the chest is liable to become fetid from the introduction of germs, and septic fever is thereby induced. I have repeatedly demonstrated these effects by omitting to wash out the pleural cavity for a day or two. I should add that I have known a complete withdrawal of the pus by a single aspiration to prove sufficient; but the probability of this result is small. Aspiration repeatedly performed has succeeded in several cases under my observation, but these cases are exceptional. There is no objection to giving aspiration a fair trial before resorting to a free opening. Indeed, this is generally advisable.

If spontaneous perforation of the chest-wall take place, as denoted by the development of a fluctuating tumor, the latter may be at once opened; but if the perforation be at a point so far above the bottom of the sac that a portion only of the pus is evacuated, more or less remaining constantly below the point of perforation, a counter opening may be requisite. Aspiration, however, may be fairly tried, before resorting to this measure, and before making an incision into the subcutaneous tumor.

If perforation of the lung take place, aspiration should be employed, and, if this do not succeed, a free incision into the chest-wall made, provided the pus be not fully discharged by expectoration. The fact that only a portion of the pus within the pleural cavity is expelled through the pulmonary orifice, is readily ascertained by means of the physical signs. In most instances, perforation of the lung converts the disease into pneumo-pyothorax, but it is stated that sometimes pus passes through the opening into the bronchial tubes, without the entrance of air into the pleural space. Such instances must be rare.

To support the powers of the system is an object of still greater importance in the treatment of suppurative, than of simple chronic, pleuritis. The importance is greater because there is more danger of death by asthenia, and, in favorable cases, the duration of the affection is longer. The measures to be employed for this object are the same in both forms of the disease.

Pleuritis with Pneumothorax. Pneumo-hydrothorax. Pneumo-pyothorax. Pneumo-hæmathorax.

The term pneumo-hydrothorax denotes the presence of air or gas and liquid in the pleural cavity. As the liquid, however, is either sero-fibrinous or purulent, hydrothorax, which signifies a purely serous liquid, is not strictly appropriate; the liquid is due to inflammation, and the affection is a variety of pleuritis. It would be more correct to say, pleuritis with pneumothorax. Pneumothorax denotes the presence of air without liquid; the latter affection is rare, but it occurs and claims separate notice.

Pneumothorax coexists with suppurative pleuritis after a spontaneous perforation of the thoracic wall, or when a fistulous opening is made; and also in the cases in which the lung is perforated from the pleural surface and a communication thus opened between the air-passages and the pleural cavity. The term *pneumo-pyothorax* denotes the presence of air and a purulent liquid. But the term pneumothorax, with or without pleuritis, is considered as denoting the presence of air in the cavity of the pleura, the air generally gaining admission from the air-passages through a perforation which, in most cases, takes place from within the lung. This perforation, in the vast majority of cases, is an accident occurring in the progress of phthisis. It has been asserted that gas may be generated by the decomposition of pus in some cases of suppurative pleuritis, and that the affection under consideration may be thus produced without perforation either of the lung or the parietes. Instances, however, of this kind, if they ever occur, must be extremely rare.

It is probable that perforation of the lung would occur much oftener than it does, were it not for the constancy with which circumscribed, dry pleuritis, leading to pleuritic adhesions, supervenes upon phthisis. Over the portions of lung in which the phthisis is seated, the pleural surfaces usually become firmly united, requiring often considerable force for their separation on post-mortem examinations. These adhesions offer an obstacle to the evacuation of purulent collections into the pleural cavity. But, occasionally, collections being situated near the superficies of the lung at a point not protected by adhesions, the membrane gives way and the evacuation is into the pleural cavity. Pleuritis, under these circumstances, is at once excited, air finds its way through the perforation, and in this way the pneumothorax becomes developed. The perforation is rarely at the summit, but is situated at the middle or inferior portion of the lung.

In like manner pleuritis with pneumothorax is produced in certain cases of circumscribed, pulmonary gangrene. The decomposed pulmonary tissues are usually evacuated into the bronchial tubes and expectorated; but sometimes, being situated near the surface, the pleura at that point becomes involved in the gangrene and gives way, leaving a perforation through which air enters the pleural cavity, and pleuritis is caused by the presence of the sphacelated matter. Several cases of this kind have come under my observation. A pulmonary abscess may open into the pleural cavity, giving rise to pleuritis with pneumothorax. It is also caused by wounds penetrating the chest-wall and lung. In a case of circumscribed gangrene under my observation, after the expectoration of the gangrenous mass hemorrhage took place into the pulmonary cavity, followed by rupture and the escape of a large quantity of blood into the pleural cavity. The loss of blood was the immediate cause of death. The amphoric signs and succussion-splashing were present. The term *pneumo-hæmathorax* expresses the conditions in this case.

Anatomical Characters.—Gas escapes with more or less force after the knife penetrates the chest, in making the post-mortem examination. If

the patient has survived sufficiently long after the perforation, the pleural cavity contains a purulent exudation in variable quantity in different cases. The air and liquid are sometimes extremely fetid, and in other cases devoid of fetor. The fetor is excessive if the affection be associated with pulmonary gangrene. After the sternum is removed, if the nozzle of a pair of bellows be inserted into the trachea, and air forced into the lung of the affected side, bubbles rising in the liquid show the fact of perforation and its situation. The size of the perforation varies. It is usually small when the affection supervenes on phthisis; but it may be quite large in cases of gangrene. The lung on the affected side, if not prevented by old adhesions, is compressed into a solid mass, as in cases of simple pleuritis with large effusion.

Clinical History.—The occurrence of perforation of the lung is usually marked by acute pain denoting the development of pleuritis. The introduction of air and the speedy effusion of liquid give rise generally to notable dyspnœa, with accelerated breathing, accompanied frequently with lividity. The pulse is in most cases rapid and feeble. These symptoms show the supervention of a serious affection of some kind, and point to the chest as its seat.

In some cases the accelerated breathing and dyspnœa continue to be prominent symptoms, the patient suffering greatly, and perhaps being unable to lie down (orthopnœa), the affection ending fatally, usually under these circumstances after the lapse of a few days, and it may end fatally in the course of a few hours. But, in other cases, the violence of the symptoms subsides after a short time, and the dyspnœa may be moderate, or wanting, save on exercise. In some instances, even considerable exercise is practicable. As regards strength and the general condition, there is much variation in different cases. In the majority of cases, patients are confined to the room and bed, but sometimes they are able to be out of doors, preserving appetite, and not presenting a notably morbid aspect. Much will, of course, depend on the condition as regards the affections of which this is a complication.

As an exception to the rule, pleuritis with pneumothorax from perforation is developed gradually and imperceptibly. It may remain for a greater or less period quite latent. In some instances the accumulation of liquid becomes large, the air disappears, and the affection is converted into simple pleuritis with effusion. In several instances of this kind which have fallen under my observation, thoracentesis was resorted to, and the communication between the air-passages and pleural cavity, through the perforation, was resumed after the liquid was withdrawn.

Diagnosis.—When this affection is developed with marked symptoms in the course of phthisis, its existence should certainly be at once suspected; but the symptoms are not sufficiently distinctive of this affection, as contrasted with pleuritis and effusion without the presence of air, to warrant a positive differential diagnosis. Moreover, as just stated, the affection is sometimes latent, the symptoms not warranting even the diagnosis of pleuritis. A positive diagnosis, in short, must be based on physical signs, and these are easily obtained and very explicit.

The presence of air in the pleural cavity renders the resonance on percussion purely tympanitic. If the quantity of liquid be small or moderate, tympanitic resonance may extend over the whole of the affected side, being propagated from the level to the bottom of the liquid. If the liquid be large or considerable in quantity, dulness or flatness will be found at the base and extending upward (the patient sitting) to a certain height, tympanitic reso-

nance existing above. Under these circumstances, the relation of resonance and dulness or flatness will always be found to vary with the changed position of the body of the patient. The tympanitic resonance sometimes has an amphoric character.

Respiratory sound is sometimes wanting over the whole of the affected side. Over the compressed lung bronchial respiration may often be found. The ordinary cavernous respiration is sometimes heard, but, in most cases, amphoric respiration and amphoric voice or echo are present, either limited or diffused over the whole of the affected side, and metallic tinkling is generally conjoined. The presence of these striking and distinctive signs renders the diagnosis easy and positive, taken in connection with other signs.

Succussion almost invariably develops a splashing sound, frequently having the same kind of musical intonation as the respiration, voice and tinkling sounds. This proof of the presence of air and liquid is positive, and it enables the diagnosis to be made in an instant.

The affected side is frequently dilated and presents the same appearances as in cases of dilatation from liquid either in simple or suppurative pleuritis.

Leyden has recently called attention to the rare occurrence of abscesses, containing air, situated just below the diaphragm, either on the right or the left side, oftener on the right, between the diaphragm and the upper surface of the liver.[1] The abscesses result from perforating ulcers of the stomach or duodenum from which gas is derived, circumscribed peritonitis having been produced. The signs of pyo-pneumothorax are present. Leyden diagnosticated the affection in two cases, each connected with perforating ulcer of the stomach. The differential points are, the presence of the respiratory murmur from the clavicle down to the third rib; the extension of the respiratory murmur downward by deep inspiration, and, at first, absence of cough and expectoration. The abscesses may burst eventually into the lungs. A capital point in the diagnosis is the history of the development of the abscess with the signs of peritonitis, following symptoms referable to the stomach or intestine.

Prognosis.—The prognosis, in cases of pleuritis with pneumothorax, is always unfavorable. In this statement traumatic cases are excluded; the prognosis in these cases is generally favorable. Of the cases of empyema in which pneumo-pyothorax is produced by perforation of lung, there is a fair prospect of recovery if other circumstances be favorable. If the affection be connected with pulmonary gangrene, death takes place generally within a short period. Other things being equal, when it occurs in the course of phthisis, a fatal termination is speedy in proportion to the progress which the latter affection has made. There is a wide variation in different cases as regards its duration before a fatal ending; in many cases it ends fatally within a few days or weeks, but sometimes life is prolonged for months or even years. It may continue for an indefinite period, the patient experiencing so little inconvenience as to consider himself in fair health. The following unique case will serve to verify this statement, and also illustrate the latency of the affection occurring in connection with phthisis:—

I received from Dr. J. H. H. Burge, of Brooklyn, N. Y., the left lung which he had removed at a post-mortem examination made two or three days before. The patient, aged eighteen, an accountant, was seized, four days before his death, with an acute affection which proved to be pneumonitis affecting the lower lobe of the right lung. At the time of the attack he considered himself in fair health. He was attended by Dr. Burge, who found the physical signs denoting pneumonitis, and the affected lobe was found after death

[1] Zeitschrift für Klinische Medicin, Bd. 1, p. 320.

in the second stage of this disease. On an examination of the chest, in addition to the pneumonitis, Dr. Burge discovered the signs of pneumo-hydrothorax affecting the left side. Metallic tinkling, and amphoric respiration and voice, were well marked. The upper portion of the chest on this side yielded a tympanitic, and the lower portion a dull resonance on percussion.

On inquiry as to the previous health, the patient declared that he was well when attacked with the acute disease; that is, four days before his death. On close questioning, however, it was ascertained that he had had a slight cough for a year, but so slight that he thought nothing of it. He was not conscious of any deficiency of breath, was not subject to pain in the side, and, in short, there were no symptoms pointing to so grave an affection as pleuritis with pneumothorax.

The left lung was completely condensed from compression. The lower lobe was readily inflated; the upper lobe but slightly, owing to the free escape of air through a perforation as large as a crow's quill, situated on the anterior aspect of this lobe, about midway from the upper to the lower extremity. On closing the aperture, this lobe was readily inflated. The perforation was gaping, the orifice being surrounded by a cartilaginous rim. On passing a probe into the aperture, it entered a small cavity of about the size of an American walnut. The cavity was smooth and lined by a membrane. This was the only cavity in the left lung, and there were no phthisical deposits. The whole surface of the lung was covered with fibrin dense and closely adherent. The pleural cavity contained more than a quart of turbid liquid which was not fetid. When this side of the chest was opened, air escaped with force, emitting no fetor. The upper portion of the right lung contained several phthisical cavities, the largest of the size of an English walnut; also, small phthisical deposits.

Treatment.—The treatment of pleuritis with pneumothorax, in most cases, embraces only palliative and sustaining measures. The severity of the pain and the distressing dyspnœa frequently call urgently for measures to procure relief. Opium, soothing applications to the chest, and the ethereal preparations are indicated for this object. The powers of the system are to be sustained by tonic remedies, alcoholic stimulants, and a nutritious diet. These measures will generally only serve to mitigate the sufferings of the patient and prolong life; and in the rare cases in which the affection continues for months, years, or indefinitely, and is not incompatible with comfortable health, there is no special treatment to be pursued, the main object being to invigorate and support the powers of the system.

If the patient suffer greatly from dyspnœa arising from dilatation of the affected side, the chest may be punctured as a palliative measure. I have resorted to this operation to the great relief of the patient. The air will be likely to reaccumulate, and the side become again dilated as before; but I have known this not to occur for some weeks, and the operation may be repeated as often as called for by the dyspnœa arising from the dilatation.

These remarks on the treatment have reference to pneumo-hydrothorax occurring in connection with phthisis, and not to the perforation of lung from without inward in cases of suppurative pleuritis. The treatment of pneumo-pyothorax, when thus secondary to the latter disease, has been already considered (*vide* page 151). It is a question whether, when occurring in cases of phthisis, a free incision into the chest and a permanent opening may not be advisable. I have resorted to this measure in a few cases with notable relief, and, apparently, life has been thereby prolonged. It is within the range of possibility that this procedure may effect a cure. If the phthisical affection be small and cease to progress, the perforation possibly may become

closed by adhesions, and recovery from the pleuritic disease take place. Considering that there is no prospect of effecting a cure by any other method of treatment, and that the condition of the patient is not injured but improved by making a free opening into the chest, there can be no objection to resorting to it.

When the chest, after perforation of the lung in cases of phthisis, becomes filled with liquid, it should not be withdrawn for a considerable period. Permanent closure of the perforation may sometimes ensue. An instance of recovery, under these circumstances, has not fallen under my observation, but I have known several weeks to elapse after aspiration before pneumothorax again occurred.

Pneumothorax.

The term pneumothorax denotes the presence of air, without liquid, in the pleural cavity. Under these circumstances, pleuritis either does not exist, or it is not accompanied by effusion. This affection is certainly extremely rare; its occurrence has been doubted, but its existence is sufficiently established. In cases of pneumothorax without pleuritis, the perforation of lung is not incident to either gangrene or phthisis, but is probably connected generally, if not invariably, with emphysema which may not be general but circumscribed. Emphysematous dilatation of the air-cells, perhaps confined to a few lobules at the margin of a lobe, or an emphysematous bleb, may lead to a minute rupture through which air is forced by the acts of breathing into the cavity of the pleura. The perforation, as remarked by Gairdner, may be no larger than a pin-hole. The presence of the air does not excite pleuritis, but the accumulation may be sufficient to compress the lung into a solid mass, as in pleuritis with large effusion, dilating the affected side, and removing the heart from its normal situation.

Pneumothorax, without effusion from pleuritis, is characterized by the absence of the symptoms and signs denoting inflammation and the presence of liquid. The patient suffers chiefly from the mechanical effects of the presence of air. These effects relate exclusively to the respiration and circulation. There is little or no febrile movement; the appetite, digestion, and nutrition are not affected, and the vital powers are maintained. If the affection were to end fatally, it would be by apnœa, assuming that pleuritis is not developed sooner or later. It is unquestionable that this affection may end in recovery. Under the influence of compression, the perforation may become sealed up by a circumscribed pleuritis with the exudation of fibrin, or by the adhesion of the pleural surfaces at the point of perforation, the lung again expanding and resuming its function. Gairdner has quoted the report of a remarkable case illustrative of the occurrence of pneumothorax without pleuritis, and of its favorable course and termination.[1] Gairdner regards this case as unique in respect of the distinctness of the clinical facts on which the diagnosis was based. A case equally striking, and not less distinct as regards the diagnosis, has fallen under my observation. The important points taken from the history of this case, which was recorded very fully, are as follows:—

A Polish peddler, aged 29, was admitted into hospital, January 29, 1856. He stated that twelve days before his admission, being apparently in perfect health, he was attacked suddenly with a sharp pain in the region of the left nipple, accompanied with shortness of breath. This occurred while he was carrying his pack which weighed about 70 pounds. He had no cough nor expectoration. The pain soon disappeared, but the want of breath obliged

[1] Clinical Medicine. Edinburgh, 1862, page 381.

him to give up his occupation and led him to the hospital. He was a vigorous man, weighing about 175 pounds. He presented a healthy aspect, complaining only of deficiency of breath on exercise. This difficulty did not prevent him from being up and walking freely about the ward.

The left side was dilated, and the intercostal depressions obliterated; the resonance over this side was purely tympanitic, and auscultation furnished a well-marked amphoric echo without any respiratory sound. Subsequently amphoric respiration became extremely well marked, together with metallic tinkling. The heart-sounds showed the heart to be to the right of the sternum.

After a month there was considerable improvement as regards the deficiency of breath on exercise. The dilatation of the left side was no longer apparent, and the intercostal depressions became visible; vesicular respiration extended from the summit to the nipple, and the amphoric sounds, with the metallic tinkling, had disappeared.

Three weeks afterwards, the patient felt sufficiently improved to leave the hospital and return to his occupation. The respiratory murmur on the left side was feeble, but everywhere appreciable, with no abnormal modification, save in intensity, and no amphoric sounds. The impulse of the heart was felt on the left side of the sternum.

The patient consulted me a month after his discharge from the hospital. He had returned to his occupation of peddling, carrying his pack on his back as before. He had experienced no difficulty from want of breath until three days before his visit to me; but for three days the deficiency of breath on exercise had been considerable. On examination of the chest, the left side was everywhere tympanitic; there was no respiratory murmur on that side, and the heart was on the right side of the sternum. No amphoric sounds. He complained of nothing but the want of breath; excepting this, he was well.

I did not see the patient afterward for eleven months. At the end of that time he called to see me with another patient. After his former call upon me he gave up peddling and became a farm-laborer. He now appeared and reported himself to be perfectly well. The respiratory murmur was everywhere heard over the left side, but was slightly weaker than on the right side. The apex-beat of the heart was in its normal situation. The left side laterally and posteriorly presented to the eye slight contraction.

This was evidently a case of simple pneumothorax, without pleuritis. A pin-hole perforation at a weak point, or the rupture of an emphysematous bleb, probably took place in consequence of the muscular exertion of carrying his pack. He had nearly recovered when, on resuming his occupation, the perforation was reopened, and the pneumothorax reproduced. Recovery again took place, and, after the lapse of several months, appeared to be permanent.

A sufficient number of cases of pneumothorax, without pleuritis, to serve as a basis for the clinical history and prognosis, are not yet available. The infrequency of the affection is such, that the collection of a considerable number of cases for analysis cannot soon be expected. The case just given, and the case reported by Gairdner, go to show that a favorable prognosis may be entertained.

As regards treatment, it is obvious that no special course of medication is called for. The compression of lung probably favors the healing up of the perforation, so that it would not be advisable to puncture the chest in order to allow the air to escape. Active exercise or muscular efforts, as in straining, are to be avoided, not only during the continuance of the affection, but for some time after recovery, lest the orifice may be reopened, as in the case just

detailed. Soothing embrocations to the chest will be useful as palliatives; but nothing can be gained by active counter-irritation. A nutritious diet may be allowed. Cathartics, diuretics, and rubefacients are not indicated.

Circumscribed Pleuritis.

The frequency with which pleuritic adhesions over a limited area are found after death, is proof that circumscribed pleuritis often occurs. But the inflammation which results in these adhesions is often subacute, and generally occurs without giving rise to much pain or other disturbance. As already stated, circumscribed pleuritis is secondary to some pulmonary affection, especially phthisis and pneumonitis. It differs from a primary general pleuritis in not giving rise to pleuritic effusion. Fibrinous exudation is sometimes small, and, perhaps, may be altogether absent, the adhesions taking place purely by a hyperplasia or proliferation of the connective tissue. Limited to the pleura investing the diaphragm (diaphragmatic or phrenic pleuritis), inflammation is supposed to give rise to symptoms which are distinctive, namely, hiccough, attended with pain, and pain referable to the diaphragm in the acts of coughing. It may be doubted, however, if these symptoms be sufficient to mark the situation of inflammation, or to distinguish inflammation from pleurodynia. If, from the symptoms, circumscribed pleuritis be suspected, the treatment indicated embraces moderate counter-irritation, soothing applications to the chest, and anodyne remedies. The successive attacks of circumscribed pleurities which occur during the progress of phthisis, and which lead to firm adhesions, are seldom accompanied by much pain, and only call for palliative measures.

Circumscribed collections of sero-fibrinous or purulent liquid are usually, if not always, preceded by general pleuritis which has led to the adhesions surrounding the space in which the liquid is contained. These collections may be situated at the lower part of the chest, between the lung and diaphragm, or between the lobes. The previous history and the appearances of the chest will generally show the prior existence of general pleuritis. The diagnosis of circumscribed collections of liquid is not always easy. For the physical signs, the reader is referred to works which treat more fully of thoracic diseases. The treatment embraces the measures for promoting absorption; and, if the liquid be purulent, this fact having been demonstrated by means of the exploring trocar, it is advisable to effect the removal of the liquid by a free opening after a trial of repeated aspirations. The latter have been successful in some cases under my observation.

Hydrothorax.

Hydrothorax, using the term correctly, is not a variety of pleuritis, but it is noticed in this connection because, as far as certain symptoms and physical signs are concerned, it has points in common with pleuritis accompanied by liquid effusion. In the proper sense of the term, it denotes a dropsical affection. The effused liquid is serum devoid of fibrin. The effusion is not a result of inflammation or any other affection of the pleural membrane, but proceeds from the conditions, relating to the blood and circulation, on which dropsical effusion in other situations depends. It very rarely, if ever, occurs alone, but is an element of general dropsy; that is, dropsical effusion exists at the same time in the peritoneal cavity and in the subcutaneous areolar tissue, the latter constituting either œdema or anasarca. As a rule, in cases of general dropsy, the hydrothorax is subsequent to the anasarca and to hydroperitoneum.

The signs which denote the presence of liquid in the pleural cavity are alike applicable to inflammatory and dropsical effusion. The proof afforded by the change of level of the liquid, corresponding with changes of the position of the body, is more constantly available in hydrothorax, because fibrin is not present to agglutinate the pleural surfaces and lead to permanent adhesions. But the distinctive feature of this affection is the existence of effusion in both pleural cavities. Hydrothorax is bilateral, provided the pleural cavity on one side be not abolished by universal adhesions due to a previous attack of pleuritis, whereas pleuritis, when it is primary, is unilateral. The amount of dropsical effusion, however, in both sides, is generally not uniform. It is not uncommon to find in the pleural cavity on one side a quantity of liquid considerably larger than is contained in the cavity on the other side. It may then be laid down as a rule, that, if the physical signs show the presence of liquid in both sides, and general dropsy coexist, the affection is hydrothorax. A friction murmur is, of course, not developed in this affection.

Symptoms denoting inflammation, namely, pain, cough, febrile movement, do not belong to the clinical history of hydrothorax The respirations are increased in frequency, and the patient suffers from deficiency of breath, or dyspnœa, in proportion to the amount of dropsical effusion. Existing in both sides, it is obvious that the embarrassment of respiration will be the same as if all the liquid were in one pleural cavity, and twice as much as if the effusion in one side were unaccompanied by an equal effusion in the other side. If there be considerable effusion, dyspnœa will be marked, amounting perhaps to orthopnœa, and death by apnœa may be due to the amount of effusion. Cardiac lesions producing obstruction of the mitral orifice, especially favor the occurrence of hydrothorax, after these lesions have led to dilatation of the right cavities of the heart.

The measures of treatment in hydrothorax are those indicated in general dropsy, and these need not be considered in this connection. Aspiration should be resorted to, as a palliative measure, if the amount of effusion be sufficiently large to occasion much suffering, although not sufficient to endanger life. If there be any danger from apnœa, aspiration is to be employed without delay. It is an unobjectionable measure. I have resorted to it frequently. As there is no obstacle to the expansion of the compressed lung in cases of hydrothorax, all the effused liquid may be at once removed without the distress which is apt to accompany aspiration in cases of pleurisy.

It should be added that, in some cases in which it is dependent on mitral obstruction, hydrothorax is greatly out of proportion to the amount of dropsical effusion in other situations; and I have repeatedly observed prompt, complete, and permanent relief procured by the hydragogue operation of elaterium in these cases.

CHAPTER IV.

ACUTE LOBAR PNEUMONITIS. PNEUMONIC FEVER.

Seat of the Inflammation. Varieties. Acute Lobar Pneumonitis—Anatomical Characters—Laws of the Disease—Clinical History—Causation—Diagnosis—Prognosis.

HAVING considered in the preceding chapters inflammation affecting the serous membrane investing the lungs, inflammation seated in the pulmonary substance or parenchyma is next to be considered. The latter is called *pneumonitis*, or *pneumonia*. Pneumonia is the name commonly used; pneumonitis is the more appropriate term, being in conformity with the plan of distinguishing inflammatory affections by the suffix *itis*. The latter term will be adopted in the headings, but elsewhere the two names will be used indifferently. The question at once arises, what constitutes the parenchyma or substance of the lungs? These terms relate to the pulmonary lobules, which are composed of air-cells, infundibula, alveolar passages, and bronchioles. A bronchus, after it enters a lobule, is called a lobular bronchus or bronchiole; it divides dichotomously once or twice and terminates in the alveolar passages, into which open the air-cells, vesicles, or alveoli. The alveolar passages also divide a few times and end in funnel-shaped spaces called infundibula, the walls of which are composed of thickly-placed air-vesicles. The lobular bronchi are devoid of cartilage-plates and of mucous glands, and are lined with a layer of low cylindrical ciliated epithelial cells. The walls of the air-cells and alveolar passages are composed of a homogeneous basement substance containing a few oval nuclei of connective tissue cells and a rich network of elastic fibres and of pulmonary capillaries. They are lined with a single layer of flat polygonal cells, some of which are small and granular, others larger and homogeneous in appearance. In acute pneumonitis the inflammation is seated in the air-cells and bronchioles. The differences in structure between the membrane composing the wall of these parts and the bronchial mucous membrane, together with a difference of function and of blood-supply, will serve to account for the fact that the inflammation in pneumonitis may be limited to the pulmonary substance, and, also, the fact that in bronchitis the inflammation rarely extends to the pulmonary parenchyma. This is in accordance with a pathological law, namely, that inflammation of a structure does not, as a rule, extend to another structure, however proximate, which has important anatomical differences, or which differs as regards its functions. Some striking examples of conservatism in disease will be found to hinge upon this pathological law. The fact, also, that the lining membrane of the air-cells is not, strictly speaking, a mucous membrane, will account for important differences pertaining to the inflammatory products of pneumonitis when compared with bronchitis and other mucous inflammations. The relation of the air-cells to the terminal branches of the pulmonary artery is also involved in the pathological phenomena of inflammation of the parenchyma of the lungs.

Acute pneumonitis, when primary, usually affects, at least, an entire lobe; and this extension of inflammation is expressed by the term *lobar pneumonitis*.

Acute Lobar Pneumonitis. Pneumonic Fever.

Acute lobar pneumonitis is the disease called by German writers *croupous pneumonia*. By some French writers it is called *fibrinous pneumonitis*. According to the view which will be presented in treating of the pathological character of the disease, each of these names is incorrect. All imply that the disease is a purely local inflammation, whereas, there are sufficient grounds for regarding it as an essential fever. A more appropriate name, therefore, is pneumonic fever. The name acute lobar pneumonitis, is here retained in conformity with usage, and for the sake of convenience for reference.

Anatomical Characters.—The first appreciable change resulting from acute inflammation is the same here as in other situations, namely, active congestion accompanied by transudation of serum. This is known as the first stage or stage of congestion or engorgement (engouement). The inflamed portion of the lung is heavier than in its healthy state ; on section the cut surfaces present a dark-red appearance, and a bloody liquid flows in abundance, which may be a little frothy. The affected portion of the lung presents the same appearance as in œdema with marked congestion. The microscopical examination shows the pulmonary capillaries widely distended with blood, and the air-cells filled with a serous fluid containing red blood-corpuscles in abundance, a few white blood-corpuscles, and larger granular cells which are the epithelial cells washed off by the watery transudation from the blood. In this stage the affected portion of the lung does not sink to the bottom in water.

In the second stage, usually called the stage of red hepatization, the air-cells and bronchioles become filled with a solid exudation and cease to contain air. The solidified lung is of a brownish-red color, non-crepitant, and presents an appearance not unlike that of the liver, whence the name hepatization. Upon its cut or torn surface it presents a very characteristic granular appearance, due to the projection of the little solid masses which distend the air-cells and bronchioles. In a lung previously affected with emphysema, these granules are very large and distinct. When examined soon after death, the cut surface is dry ; later, a viscid, turbid, reddish fluid may be made to escape. The substance of the lung breaks down under the pressure of the finger more readily than in its healthy state ; that is, it is more friable. Its volume is about equal to that of the lung in a state of full inspiration, and it does not collapse when the chest is opened. Its weight is much increased ; a single lobe solidified by inflammatory exudation increases in weight from one to two pounds, and an entire lung solidified may acquire an additional weight of four pounds. Owing to the absence of air, portions of the solidified lung sink when thrown into water. Examined with the microscope, the substance blocking up the air-cells and small bronchi is found to be composed of a network of fibrillated fibrin containing in its meshes a large number of pus-cells or white blood-corpuscles, and of red blood-corpuscles. A few desquamated epithelial cells of the alveoli and a variable amount of amorphous, granular matter are also present. The reddish color of the lung in this stage is probably due to the large number of red blood-corpuscles present in the exudation. Some of the air-cells often appear to be filled with hardly anything except fibrin and red blood-corpuscles, making the impression of an extravasation of blood, but probably most of the red blood-corpuscles escape by diapedesis. There can be little doubt that the pus-cells are emigrated white blood-corpuscles. The lung texture is not essentially altered by the inflammatory process. It contains, especially in the interlobular connective tissue, some emigrant cells.

When the brownish-red color of the solidified lung gives place to a gray

color, the lung is said to be in the stage of gray hepatization. The granular appearance is then less distinct and the surface moist. The red blood-corpuscles are less in number, but the pus-cells are abundant and contain molecules of fat. The lung may present the appearance of gray hepatization after death within a few days from the onset of the disease, or the aspect may be that of red hepatization after the disease has lasted two weeks or more. Most frequently the lung is found in the condition of mottled hepatization, that is of mixed gray and red. It is usually considered that gray hepatization is a later stage of red hepatization, when the inflammatory products are in process of absorption. Absorption may take place with great rapidity. The statement by Rindfleisch, and others, that the greater part of the exudation is expectorated, is certainly incorrect. The matter expectorated, in general, bears no proportion to the quantity of exudation; and there are cases in which the exudation disappears without any expectoration.

In this third stage, or stage of absorption, the red blood-corpuscles lose their coloring matter, the pus-cells undergo fatty degeneration, the fibrin becomes granular, an effusion of serum takes place, so that a kind of granulo-fatty emulsion is formed suitable for absorption by the lymphatics and blood-vessels. It must be said, however, that these usually accepted details of the process of absorption are the result of deduction rather than of actual observation. In favorable cases, after the removal of the exudation, the air-cells are found to have sustained no damage. The pulmonary structure remains intact while the exudation remains, and its functional capacity is fully restored after the exudation disappears.

When after death the color of the inflamed lung is yellow or grayish-yellow, the granular appearance absent, the tissue soft and exuding a creamy fluid, the lung is said to be in the condition of purulent infiltration. The exudation which fills the air-cells consists almost wholly of pus, and pus-cells are present abundantly in the interlobular tissue, but the lung tissue is not broken down. This condition of purulent infiltration is thought to favor the formation of pulmonary abscesses in which collections of pus take place in cavities resulting from breaking down of the lung tissue. Gangrene of the affected portion of lungs sometimes occurs, but this, as well as the occurrence of abscess, is extremely rare. Many writers admit a very infrequent termination of lobar pneumonitis; namely, in cheesy metamorphosis and phthisis. But Buhl and other writers deny that caseation of the products of lobar pneumonitis ever occurs.

Pleuritis with fibrinous exudation is developed in the portion of the pleura covering the affected lobe or lobes of the lung. This concurrent pleuritis is never absent except in those rare cases in which the pneumonitis has not extended to the surface of the lung. The pleuritis is circumscribed and dry; much liquid effusion occurs only as an exception to the rule. To these exceptional cases with liquid effusion, may be applied the term *pleuro-pneumonia*, although in a strict sense nearly every case of pneumonia is pleuro-pneumonia.

More or less bronchitis, affecting the bronchial tubes within the affected lobe or lobes, usually exists with pneumonitis. In some cases, however, the pneumonitis passes through its whole course without affording any evidence of this circumscribed bronchitis. Bronchitis affecting the bronchial tubes of both lungs is sometimes, but rarely, present with pneumonitis. When these two affections are combined, it is accidental; bronchitis, as the primary affection, does not tend to the development of pneumonitis, and the latter has no tendency to give rise to bronchitis save within the affected lobe or lobes.

To the foregoing sketch of the anatomical characters may be added certain laws of the disease, which are best presented in this connection. One of

these relates to the situation of the pulmonary affection. Pneumonitis attacks, in the great majority of cases, the lower lobe, and the lower lobe of the right, oftener than of the left, lung. Exceptionally, it sometimes attacks primarily an upper lobe, and in these cases, as a rule, the disease is more severe; but to this rule there are exceptions. The disease very rarely, if ever, attacks two lobes simultaneously, but it invades, not infrequently, in succession a second and even a third lobe. The inflammation does not extend from one lobe to another, but, whenever a new lobe is affected, it is the seat of a new invasion. The lobes of one lung may be successively invaded, or a single lobe on both sides; or, an entire lung being first affected, a lobe of the other lung may be attacked. In the two latter cases the pneumonitis is said to be double.

The inflammation extends at least over an entire lobe, as the name lobar pneumonitis implies, in the great majority of cases. There are exceptions to this rule. I have known some instances in which the physical signs clearly showed the occurrence of inflammation extending over a limited area, without any evidence of the circumscribed pneumonitis being a complication of any other pulmonary disease. In a lobe invaded secondarily, that is, one lobe being already affected, the inflammation is sometimes found after death to have extended over a portion only of the lobe. This fact I have repeatedly noted, but, perhaps, had the life of the patients been prolonged, the whole of the lobe would have been affected.

The whole of the lobe first invaded is not at once affected. The inflammation begins at a certain point, or at several distinct points, and extends from lobules to lobules until the entire lobe is involved. The point or points of departure may be at either the upper or lower extremity of the lobe, and at either the superficies or centre of the lobe. The diffusion of the inflammation over the lobe takes place with more or less rapidity; sometimes a few hours suffice, but in some cases it occupies several days. The progress of the solidification from the exudation may be determined very accurately from day to day, or from hour to hour, by means of physical signs.

The inflammation very rarely ends with the occurrence of engorgement only, without exudation. Solidification almost always occurs, and, when the inflammation is not secondary to another pulmonary disease, usually extends over the lobe or lobes invaded.

With respect to the situation and extent of the affection, the following are the results of an analysis of 121 cases:[1] In 29 cases it was limited to the lower lobe of the *right*, and in 25 cases to the lower lobe of the *left* lung. It extended over the whole of the *right* lung in 27, and over the whole of the *left* lung in 9 cases. It was limited to the upper lobe of the *right* lung in 8, and to the upper lobe of the *left* lung in 3 cases. It was seated in the lower lobe of both lungs in 8 cases.

Clinical History.—The division of acute pneumonitis into stages is based upon differences as regards the anatomical characters at different periods of the disease. The *first* stage embraces the period during which the affected lobe is in the state of active congestion or engorgement. This stage is called the stage of engorgement. The disease is considered as passing into the *second* stage when the affected lobe, or a greater part of it, has become solidified by the inflammatory exudation. This stage is called the stage of solidification or hepatization. In the *third* stage the affected lobe is in one of two conditions. If the disease pursue a favorable course, the third stage

[1] Clinical Report on Pneumonia, based on an Analysis of 133 Cases. By the Author. *Vide* American Journal of the Medical Sciences, January, 1861.

begins when it is evident that absorption of the exuded matter is going on, and convalescence takes place during this period. This may be called the stage of resolution. If the disease pursue an unfavorable course, the third stage is one of suppuration or purulent infiltration, and this stage may be called the purulent or suppurative stage. If this stage occur, the disease generally ends fatally.

The duration of each of these stages varies much in different cases. The stage of engorgement may last but for a few hours. I have known an entire lobe to be solidified by two pounds of exudation matter, as determined after death, in less than twelve hours. Not infrequently this stage does not extend beyond twenty-four hours. But sometimes the solidification occupies two, three, or four days, and in some cases even a longer period. In the majority of cases this stage is from twenty-four to forty-eight hours in duration. The stage of solidification may also be of short duration. I have known resolution to commence and make considerable progress in twenty hours. But its commencement may not be evident for two, three, or four days, or even for a considerably longer period. In the majority of cases the duration of this stage is from two to four days. The stage of resolution is still more variable. There is a notable difference in different cases as regards the rapidity or slowness with which the solidifying deposit is removed. It is very rarely the case that the resolution is completed in less than three or four days, and generally eight or ten days are required. In some cases two or three weeks elapse before the air-cells are restored to their normal condition, and occasionally the resolving process is even more protracted. If the disease pass into the purulent stage, death usually takes place within a few days; but if the disease ends in recovery, many days and perhaps weeks elapse before the normal condition is restored.

In the great majority of cases, acute pneumonitis commences with a well-pronounced chill, frequently accompanied by rigors. The thermometer in the axilla shows an increase of temperature, although coldness exists as a subjective symptom. The invasion is usually abrupt, with few or no premonitions. The attack is apt to occur during the night. Coincident with, or speedily following, the chill, is the occurrence of pain. Sometimes, however, pain is not felt until several hours after the chill. The pain is frequently severe. It is acute, lancinating, and in all respects identical with the pain in acute pleuritis. It proceeds from the pleuritis developed in conjunction with the pneumonitis. As a rule, the intensity of the pain is in proportion to the amount of coexisting pleuritis; but it is true alike of pleuritis thus developed as a complication, and when it occurs primarily, that it is sometimes attended with little or no pain. Cases of pneumonitis differ considerably as regards this symptom; it may be quite prominent, or present in a moderate degree, or altogether wanting. The pain is usually referred to a circumscribed space at or near the nipple of the affected side. This limitation of the pain is a point distinctive of pneumonitis as compared with pleuritis.

Cough is usually present at, or soon after, the invasion. It is more or less prominent. It is sometimes wanting. It is painful in proportion as pain is a prominent symptom irrespective of the cough. The cough is frequently accompanied by expectoration. The matter at first expectorated is scanty, transparent, and viscid; and, in a certain proportion of cases, it soon assumes characters which are highly distinctive of the disease. It becomes semi-transparent, adhesive, and has a reddish tint like that of iron rust; hence it is commonly known as the rusty expectoration. This appearance is due to a small quantity of blood which has become intimately mixed with the matter in its passage from the smaller to the larger bronchial tubes. The adhesiveness is such that when a considerable quantity has accumulated, it adheres

so closely to the bottom of the vessel as to remain when the vessel is inverted. The rusty expectoration is by no means uniformly present. The matter is in some cases semi-transparent and adhesive without the reddish tint. It may have a yellowish tint as if mixed with a little bile, which, however, is not the fact. It sometimes contains blood in abundance; and when the blood is of a dark color it is what is called the prune-juice expectoration. It is to be borne in mind that expectoration, in some cases of pneumonitis, is entirely wanting.

Pyrexia exists at the outset, together with pain in the head, loss of appetite, thirst, prostration, heat of skin, etc. The pulse varies much in frequency in different cases, ranging from 80 to 120, and is more or less full and hard. The thermometer in the axilla indicates more or less increase of heat, the increase, in mild cases, not exceeding 104° F.; an increase above this amount always denotes severity of the disease. A sudden increase of temperature points to the invasion of a new lobe or some intercurrent affection. Cases differ greatly as regards general or constitutional disturbance, the system being much more tolerant of the disease in some persons than in others.

The respirations are increased in frequency. This may depend on the pleuritic pain if it be marked, and also on the interruption of the function of hæmatosis in the portion of lung affected.

These are the important symptoms belonging to the clinical history of the commencement and during the first stage of the disease. During the stage of solidification, the symptoms change. Pain, if it have existed, diminishes or ceases. Cough and expectoration continue, but the cough is less hard and painful, and the expectoration is effected with more facility. The matter expectorated loses its rusty appearance, becomes opaque, less adhesive, and more abundant. It is now the expectoration of resolving bronchitis. It is furnished chiefly by the bronchial tubes within the affected portion of lung, and is abundant in proportion as the bronchial mucous membrane is involved in the inflammation. On microscopical examination of the sputa, fibrinous casts of the minute bronchial tubes may be found. The pyrexia continues, but with diminished intensity. The pulse in this stage may be small and deficient in strength, especially if more than one lobe be involved, owing to the obstruction to the pulmonary circulation, which diminishes the quantity of blood received from the lungs by the left auricle; and owing also to the amount of material withdrawn from the blood and deposited in the air-cells. The respirations are increased in frequency out of proportion to the increased frequency of the heart's action, in consequence of the solidified portion of lung taking no part in the respiratory function.

These are the modifications of the symptoms, assuming a single lobe only to be affected, and that the course of the disease is favorable. The invasion of another lobe is rarely accompanied by a chill. The pyrexia persists or is increased, and the respirations become more frequent, accompanied perhaps by labor of breathing, marked dilatation of the alæ nasi, and dyspnœa. The affection, however, of an entire lung does not always give rise to symptoms denoting great gravity of disease. The pyrexia is not always intense, and may be slight; the respirations may be but little increased in frequency; cough and expectoration may be not only not prominent but wanting, and the system may be but little disturbed.

The symptoms during the stage of resolution denote progressive improvement. The pyrexia diminishes and ceases. The cough and expectoration become less and less, the respirations resume their normal frequency, the appetite returns, the strength is increased, and, in short, convalescence is declared. If, however, the disease pass into the stage of suppuration, the symptoms denote an unfavorable course. The pulse becomes more and more frequent and feeble. The expectoration is abundant and purulent. The res-

pirations are frequent. The strength of the patient fails, and death takes place by asthenia, the accumulation of morbid products in the air-tubes frequently contributing to the fatal termination.

There are certain symptoms belonging to the clinical history of pneumonitis, which are not included in the foregoing sketch of its symptomatology. One of these relates to the urine. While the process of exudation is going on, and after solidification has taken place, until resolution begins, the chlorides frequently are greatly diminished, or disappear from the urine. This is ascertained by adding a solution of the nitrate of silver, having previously added a few drops of pure nitric acid. This delicate test shows the presence of a small quantity of the chlorides in the form of a cloudy precipitate. During the period just stated, if the chlorides be deficient or absent, the addition of the nitrate of silver produces little or no effect upon the urine. The precipitate is manifest as soon as the resolution commences, and increases until the condition of the health in this regard is regained. The disappearance of the chlorides from the urine is not peculiar to pneumonitis. It is observed in other diseases. It is not, therefore, a diagnostic criterion of the disease, but it constitutes evidence either that the exudation is going on, or that resolution has not begun. It is stated that the chlorides are found in abundance in the matter expectorated during the time of their disappearance from the urine. The quantity of urine is in general more or less diminished. The urea eliminated exceeds the amount in health, and, owing to the diminished quantity of water, the urates are often deposited in abundance when the urine becomes cold. The increase of urea denotes an abnormal secondary or destructive assimilation. It is not uncommon for the urine to contain a trace or a moderate quantity of albumen. The presence of albumen is probably due to systemic venous congestion or to an altered condition of the blood as in other acute general diseases. Albumen in abundance in the urine denotes coexisting renal disease.

Delirium not infrequently occurs in acute pneumonitis. It may be mild, and merely incidental to the pyrexia. But it is sometimes a prominent symptom. It may be active, the patient attempting to get out of bed, resisting efforts of restraint, and perhaps using violence; or it may be of the low, incoherent, muttering kind, such as occurs in typhoid fever. Delirium is more apt to occur if the upper lobe be affected, than if the affection be limited to the lower lobe. It is evidence of gravity of the disease in proportion as it is prominent, active, and persisting.

A dusky redness of one or both cheeks, the margins of the redness being abruptly defined, is frequently observed, and, if the hectic flush of pulmonary tuberculosis be excluded, is quite distinctive of acute pneumonitis. When confined to one cheek, it does not follow, as was formerly supposed, that the pulmonary inflammation is seated on the same side. It is not uncommon for an herpetic eruption to occur upon the face, more especially around the mouth.

Slight jaundice is an occasional concomitant. Its occurrence is probably accidental. At all events, it is not associated often enough to show any pathological connection between pneumonitis and hepatic disease. Owing to the accumulation of blood in the right cavities of the heart, and the consequent congestion of the systemic veins, the liver sometimes becomes more or less enlarged.

The occurrence of abscess and gangrene is accompanied by symptomatic phenomena denoting these events. The collection of pus in an abscess leads to a sudden and copious purulent expectoration, if the life of the patient be sufficiently prolonged; and the existence of a cavity may be determinable by physical signs. This is a grave event, but it by no means necessarily renders

the disease fatal. It occurred in 4 out of 133 cases which I recorded and analyzed, and two of these four cases ended in recovery. I have notes of a case, in addition to the four cases just referred to, in which a series of purulent collections were expectorated, and the recovery was complete. The infrequency of gangrene is shown by its having occurred in but one of 133 cases. The disease proved fatal in that case. Since the analysis of these cases, I have known gangrene to occur, to a limited extent, in a case which ended in recovery. Its occurrence is shown by the characteristic fetor attending expectoration, together with the appearance of decomposed pulmonary tissue in the matter expectorated.

The combination of other affections with acute pneumonitis will, of course, involve the addition of symptoms derived therefrom. In malarial districts it may be conjoined with periodical fever. This is an important complication as regards danger and therapeutical indications. The existence of the pneumonitis may serve to interrupt, to a greater or less extent, the regular succession of periodical paroxysms, and the latter may tend to obscure the phenomena of the pulmonary affection. Pneumonitis occurring in the intemperate is liable to lead to the development of delirium tremens. The complication is always serious, and is important with reference to treatment. It occurred in 8 of 133 cases. Pericarditis is another grave complication. This occurred in 8 of 133 cases.

The supervention of certain symptoms is expressed by the term *typhoid pneumonitis*. This term denotes the existence of symptoms analogous to those which belong to typhoid fever, of which the most prominent is low, muttering delirium. A distinction is here to be made between typhoid pneumonitis and typhoid fever with pneumonitis as a complication. Pneumonitis is liable to be developed in the course of typhoid fever, the latter being the primary affection; but in the so-called typhoid pneumonitis, the latter is the disease, certain of the typhoid phenomena being superadded. In other words, the typhoid state may be developed in connection with pneumonitis, as with other affections, but this typhoid state does not involve the essential fever designated as typhoid.

The duration of acute pneumonitis, when uncomplicated, varies within pretty wide limits. Dating from the attack to the time when the patient could be pronounced convalescent, in 30 cases, the shortest was 5, and the longest 23 days. The mean duration was a fraction over 12 days. In 11 fatal cases, the shortest duration from the attack to the time of death, was 3, and the longest 20 days, the mean duration being a fraction over 10 days.

A notable decrease of temperature sometimes precedes the fall of the pulse and improvement in other symptoms; and the defervescence, if the disease be uncomplicated, is usually rapid. It is then said to end by crisis instead of lysis. The pulse during convalescence is not infrequently below the normal frequency, falling in some cases to forty per minute.

CAUSATION.—Statistics show that no period of life involves either exemption from, or a notable proclivity to, this disease. It occurs under 5 years of age, but not often. Cases are less infrequent between the ages of 5 and 10. Of 118 cases, the patients all were over ten years of age, 13 were under 20; 44 between 20 and 30 years; 37 were between 30 and 40 years; 17 were between 40 and 50 years; 7 were between 50 and 60 years, and in no case was the age over 60. Cases, however, are not infrequent after the age last named. The disease occurs much oftener among males than females. The analysis of my cases with reference to occupation does not show that any particular calling predisposes to this disease, but the proportion of laborers engaged in out-door work over those employed within doors, shows that

they are most liable to the disease who are exposed to the vicissitudes of the weather. Not infrequently the attack is excited by some unusual exposure, such as working in the cold and wet, or sleeping out of doors at night. The large proportion of hospital cases in which patients are addicted to excessive drinking, shows that causative influences proceed from intemperance. In 10 of 37 cases in which the habits were noted, the attack followed a debauch. It is questionable whether the abuse of alcohol acts directly as a cause; probably the disease is caused by circumstances incidental to intemperance, such as exposure to cold, etc., these acting as exciting causes.

The association of periodical fever and pneumonitis has already been adverted to. My observations do not show the existence of any pathological connection between these affections. There is no ground for the conclusion that persons subject to intermittent fever are thereby more prone to pneumonitis, nor that the latter affection tends to reproduce an attack of the former. Their coexistence is due to the coincidence of the causes proper to each.

With respect to causative influences pertaining to other pulmonary affections, facts show that bronchitis does not eventuate in pneumonitis. The same is true of pleuritis. Tuberculous patients are not particularly prone to the disease, and when it does supervene, it may, or may not, affect the upper lobe in which the deposit of tubercle is most abundant. Certain pulmonary affections, namely, emphysema, asthma, and chronic pleuritis, are so infrequently associated with pneumonitis as to show that, instead of involving a predisposition to this disease, they afford more or less protection against it. Pneumonitis is not often developed in persons affected with organic disease of the heart.

Pneumonitis occurs as a complication of other than pulmonary diseases. It is not infrequently developed in the course of typhus and typhoid fever, rubeola, dysentery, etc. The different affections of the kidneys have been supposed to stand in a causative relation to it. My own experience does not furnish evidence of such a relation. In not one of 133 cases analyzed was the disease preceded by albuminuria.

It occurs in certain seasons of the year in preference to other seasons. It occurs everywhere much oftener during the winter than during the summer months, and in our Northern States cases are more frequent in the spring months than at any other season. Forty-nine cases recorded at Buffalo were distributed among the different months as follows: January, 7; February, 2; March, 13; April, 9; May, 3; July, 3; August, *none;* September, 2; October, 1; November, 1; December, 5. At New Orleans, cases are most numerous during the winter months. The analysis of 296 cases, by Grisolle, shows the largest number of cases in February, March, April, and May, in Paris, the relative proportion of cases in June, August, September, and October being small.

In this country the disease occurs in the Middle and Southern, much oftener than in the Northern, States. It prevails much more in some years than in others. In sections of the Southern States it prevails at times sufficiently to be considered as endemic. It is the prevalent disease during the winter months in these States, and affecting especially the negro population, often proves the scourge of the sugar and cotton plantations of the South. It is a severer disease in the southern sections of the country than at the North, being more liable to extend beyond a single lobe, and proving fatal in a larger proportion of cases. This liability is greater, in the same district, in some years than in others. In some years, also, there is an unusual tendency in the disease to attack primarily an upper lobe. Such a tendency is manifest at the time of writing these remarks. Within two months (October and November) in hospital practice, I have met with five cases in which the dis-

ease has been limited to an upper lobe, being about one-half the cases which have occurred under my observation during this period.

In a large proportion of the cases of acute pneumonitis, the disease is developed spontaneously; that is, it is not referable to any obvious causative agency. When it appears to follow exposure to cold, it is probable that this acts only as an exciting cause, co-operating with the action of a special cause. It may be affirmed that traumatic causes, such as injuries of the chest, never give rise to acute lobar pneumonitis.

DIAGNOSIS.—Acute pneumonitis, in some cases, is accompanied by symptoms which are highly distinctive. If a patient be seized with a chill, followed by febrile movement, together with a pleuritic stitch referred to a circumscribed space near the nipple, and the characteristic rusty expectoration occur, the diagnosis is readily made without the aid of physical signs. But these symptoms are by no means constantly present. The disease is not infrequently entirely latent as regards diagnostic symptoms, and it is often overlooked by those who do not employ physical exploration. Even if its existence be revealed by symptoms, irrespective of signs, the situation and extent of the affection can only be ascertained by means of the latter. With the aid of signs, the diagnosis in the great majority of cases is made without difficulty. The diagnostic symptoms are especially apt to be absent and the disease to be developed insidiously when it is associated with other diseases. Not infrequently an examination of the chest reveals its existence unexpectedly. I have been accustomed to characterize it, under these circumstances, as *sneaking pneumonia*, using the language of personification which is so often used in speaking or writing of diseases. The term "asthenic pneumonia" has been applied to it when the symptomatic characters which belong to typical cases are wanting. On the other hand, the term "frank pneumonia" is often used to distinguish cases in which these characters are well marked.

Patients with this disease do not always at once take to the bed. It is not very uncommon to meet with cases in dispensary practice, the disease having gone on to the second stage. Recently (1879) a young woman consulted me at my house, complaining chiefly of weakness and loss of appetite, with a slight cough. The temperature in the axilla was 103°, and physical exploration showed solidification of the entire lower lobe of the right lung. She had taken a long drive the previous day, thinking it might be of benefit to her, and she had come two miles to see me. The history rendered it certain that the disease was acute lobar pneumonitis. These might be distinguished as "walking cases."

In the first stage, the signs on which the diagnosis is to be based are, slight or moderate dulness on percussion, and the crepitant râle. The latter, if persistent and well marked, is almost pathognomonic. Care must be taken, however, not to confound this râle with the subcrepitant, its distinctive characters being its fineness, dryness, and limitation to inspiration. With a distinct appreciation of these characters, it should never be confounded with the subcrepitant râle, which, however fine, is a moist, bubbling sound, and liable to be heard in expiration as well as in inspiration. But the crepitant râle is not uniformly present. In its absence, a positive diagnosis may require some delay, until a sufficient number of lobules are solidified to give rise to an appreciable modification of the respiratory murmur. The modification is that which I have described under the name broncho-vesicular respiration;[1] a modification approximating, more or less, toward the bronchial

[1] *Vide* Physical Exploration of the Chest and the Diagnosis of Diseases affecting the Respiratory Organs. Second Edition, 1866. Also, Manual of Auscultation and Percussion. Second Edition, 1879.

or tubular respiration. With the occurrence of this modification, the dulness on percussion becomes more marked. In most cases, if the disease be observed from the beginning, the signs of the second stage are soon declared. In hospital practice, and in many cases in private practice, the disease has already advanced to this stage when the patient is first examined.

When the solidification is sufficient in degree, and has extended sufficiently over the affected lobe to furnish the signs of that condition, the diagnosis, if it have not been already fully made, is rendered clear by the presence of these signs. Bronchial respiration, bronchophony, and whispering bronchophony are the signs denoting the condition of solidification. They are first manifested over a limited portion of the affected lobe, and are thence diffused over its whole extent, either quickly or gradually, according to the rapidity or slowness with which the whole lobe becomes solidified. The progress of the second stage may be determined by the extension of these signs. They are generally all present, but, if one be wanting, the others will be likely to be present; it is exceedingly rare for all to be absent. Dulness on percussion is now marked, amounting, perhaps, nearly or quite to flatness. This dulness or flatness extends over a space corresponding to that occupied by the solidified lobe; or, percussing anteriorly, the boundary line separating the dulness or flatness from the pulmonary resonance, is found to pursue a course coincident with the situation of the interlobular fissure, namely, obliquely upward and outward from the fourth or fifth costal cartilage toward the axilla. And this boundary line is the same whether the patient be sitting or lying upon the back. This is assuming that the pleural cavity does not contain liquid, which is ascertained by the signs indicated in connection with the diagnosis of simple pleuritis. The crepitant râle, if it have existed in the first stage, may continue, more or less diminished, during the second stage, or it may disappear after the affected side has become solidified. The moist and dry bronchial râles are liable to be heard in this stage.

The invasion of a second or third lobe is denoted by dulness on percussion and the auscultatory signs of solidification, the crepitant râle rarely occurring in the lobes which become secondarily attacked. By means of the signs of solidification, namely, broncho-vesicular and bronchial respiration, and bronchophony with the loud and whispered voice, the extension of the affection to other lobes, in addition to the one first invaded, is speedily ascertained. If the upper lobe become solidified, it is sometimes flat on percussion, and sometimes it yields a tympanitic resonance which occasionally has an amphoric intonation.

The commencement of resolution and its progress from day to day are shown by modifications of the signs denoting solidification. The bronchial respiration gives place to the broncho-vesicular, and the latter progressively approaches more and more to the normal vesicular murmur, into which it becomes finally merged when the resolution is completed. The characters of bronchophony are gradually lost. Dulness on percussion becomes less and less marked, but some degree of dulness over the affected lobe or lobes continues for some time after the auscultatory signs show the exudation to have been removed. During the progress of resolution, the subcrepitant râle is frequently heard, and sometimes the crepitant râle reappears constituting the crepitant râle redux.

If the disease pass into the stage of suppuration, the dulness or flatness on percussion continues, and the moist bronchial râles, due to pus in the air-tubes, are prominent. The auscultatory signs of solidification continue, but are less marked. If abscess of the lung take place, and the patient's life be prolonged until a discharge of the pus into the bronchial tubes occur, cavernous respiration may become well marked.

A coexisting liquid effusion, occurring exceptionally, is shown by signs already noticed. Under these circumstances, the affected side may be dilated, the intercostal depressions are obliterated, and obvious contraction of the chest may follow recovery.

PROGNOSIS.—The prognosis, in cases of acute pneumonitis, will depend on the extent of lung involved, the intensity of the pyrexia, the diseases with which it may be connected as an intercurrent affection, its complications, the previous constitution of the patient, etc. These circumstances will affect the gravity and danger to such a degree that, in respect of the probable termination, cases differ as much as if they were cases of different diseases. Occurring as a primary disease, limited to a lower lobe, remaining uncomplicated, and the person affected having a fair constitution, the intrinsic tendency is to recovery; indeed, recovery is not only the rule, but the exceptions are exceedingly unfrequent. Of the 133 cases which I have analyzed, in only two of the fatal cases was the disease limited to one lobe and not complicated or associated with other important affections. In one of these two cases the inflammation was seated in an upper lobe and eventuated in abscess. In the other case the absence of complications was predicated on the examinations during life, a post-mortem examination not having been made.

Even if more than one lobe be involved, provided the disease be primary and uncomplicated, a favorable termination may reasonably be expected in a subject not enfeebled by age or other causes. I have known recovery to take place in a case in which an entire lung was involved, and the patient situated under as unfavorable hygienic circumstances as could well be imagined. In the case referred to, the patient was attacked when working alone in a shanty, there being, at the time, two inches of water on the ground. The case occurred, during the winter season, in the swamp near New Orleans. After the attack he was unable to leave the bed for any purpose for a week, and during this time he was entirely alone. He had a quart of brandy, which he drank during the week. His habits, as he stated, were temperate. At the end of a week he was visited by some one (not a physician) who gave him thirty grains of calomel. After this he remained alone for ten days. A friend at length came to him, gave him some doses of quinia, and removed him first to his own house, and afterward to the Charity Hospital of New Orleans. The physical signs, on his admission into the hospital, showed pneumonitis affecting the whole of the right lung, and resolution progressing. He remained in hospital six days, convalescence going on rapidly, and at the end of that time he was well enough to be discharged.

The gravity and danger, then, in cases of this disease, proceed, not so much from the disease *per se*, as from coexisting affections and other incidental circumstances. Developed in the course of continued fever, measles, or other diseases, it may lead to a fatal termination. In aged and feeble persons it may end fatally without any coexisting disease, especially if more than a single lobe be involved. Occurring in persons affected with organic disease of the heart, it is likely to prove a serious affection. I have known it to destroy life in the first stage when developed in this connection. The pulmonary symptoms are rendered more severe and the danger is increased by antecedent emphysema.

The complications which are apt to render it fatal are pericarditis, intermittent fever, and delirium tremens. These complications invest cases with much gravity and danger, but recovery takes place, in a certain proportion of cases, notwithstanding their existence. The gravity and danger from these complications are of course greater if the disease invade more than a lobe.

There is a liability in the course of this disease to an occurrence which claims especial notice, namely, coagulation of fibrin in the right auricle or ventricle, that is, to heart thrombus. This is of not infrequent occurrence in fatal cases of pneumonitis. It occurs especially when an entire lung becomes involved, and in cases of double pneumonitis. In such cases, the obstruction to the passage of blood through the lungs, caused by the presence of the exudation, involves an over-accumulation of blood within the right cavities of the heart. The right ventricle and auricle are enfeebled by distension, and this condition, in conjunction with the increase of fibrin in the blood (hyperinosis), leads to coagulation. On examination after death, in the right ventricle is a dense thrombus devoid of red corpuscles, closely intertwined with the tendinous cords, and adherent to the ventricular walls. Thrombi formed *ante mortem* and not infrequently the immediate cause of death, are to be distinguished from those produced in the last moments of life, and *post-mortem* clots (*vide* Part I. page 29). Their formation may sometimes be determined with much confidence during life. In a case presenting no symptoms which denote imminent danger, a sudden change takes place for the worse; the circulation is notably disturbed, as shown by frequency, feebleness, and irregularity of the pulse; there is a sense of the want of air; the expression is haggard and anxious, cyanosis is more or less marked; the patient falls speedily into a moribund state, and this unexpected change is not connected with an extension of the disease to a new lobe or any newly developed inflammatory complication. Under these circumstances the formation of a heart-clot is highly probable. The probability of this accident is rendered still stronger if a newly developed cardiac murmur be discovered and referred to the right side of the heart; and it is sometimes practicable to appreciate the absence of the tricuspid valvular element of the first sound of the heart.

The invasion of a second lobe, in a feeble subject, may be accompanied by notable prostration, amounting sometimes to a state of collapse. In the previous editions of this work, the synopsis of a case was given, in which the patient was apparently moribund, restoration taking place under the free administration of alcohol. I have met with cases in which a primary invasion, occurring in aged persons, produced such a degree of prostration and disturbance of the heart's action, that death by rapid asthenia seemed imminent, life being apparently saved by free alcoholic stimulation.

As regards anatomical changes pertaining to the lungs, gangrene, abscess, and the suppurative stage of the disease render the prognosis extremely unfavorable. Yet I have known recovery to take place in cases in which the symptoms denoted the occurrence of these events.

Symptoms which are unfavorable as prognostics are the following:—Frequency and feebleness of the pulse; great frequency and labor of respiration; lividity of the prolabia and face; an abundant purulent or muco-purulent expectoration; bloody, dark-colored sputa, commonly known as the prune-juice expectoration; active, violent delirium; low, muttering delirium, with prostration and subsultus tendinum, constituting the typhoid state. Cases presenting the symptoms last stated are often distinguished as cases of typhoid pneumonitis.

In the majority of fatal cases of acute pneumonitis, death takes place by asthenia in combination with apnœa, the former predominating. Death purely by apnœa may occur if two or three lobes become rapidly involved, but its occurrence is rare. The occurrence of an abundant pleuritic effusion increases the danger from apnœa. So, also, the occurrence of the disease in persons affected with emphysema, and in cases of pertussis. In general, life is not lost in consequence of the extent of interference with respiration, but, owing to concomitant affections or other circumstances, the vital powers give way, and

the patient dies from exhaustion. This is an important fact in its bearing on thereapeutical indications.

When convalescence takes place, it generally progresses until the recovery is complete. The disease never becomes chronic, unless it may be so considered when resolution is extremely slow. A relapse never takes place. It is rare for phthisis to become developed as a sequel of lobar pneumonitis. When phthisis appears to be a sequel, it probably existed prior to the pneumonitis. If the upper lobe be primarily attacked, it has been supposed that the prior existence of phthisis may be inferred. There may be some ground for this inference, but I have often known the inflammation to be limited to the upper lobe in many cases in which the anterior and subsequent history furnished no evidence of phthisis.

CHAPTER V.

ACUTE LOBAR PNEUMONITIS—(Continued). VARIETIES OF PNEUMONITIS.

Treatment of Acute Lobar Pneumonitis—Pneumonitis in Young Children—Pathological Character of Acute Lobar Pneumonitis—Circumscribed Pneumonitis—Embolic Pneumonitis—Pyæmic Abscesses in the Lungs—Pigment, or Brown Induration—Pneumonokoniosis—Lobular Pneumonitis—Atelectasis—Pleurodynia and Intercostal Neuralgia—Hyperæmia of Lungs—Hypostatic Congestion—Hypostatic Pneumonitis.

THE different stages of acute pneumonitis furnishing different therapeutical indications, the treatment of each stage is to be considered separately.

The question whether the disease may be arrested, relates to the first stage. Measures which have heretofore been considered as abortive, are bloodletting, cathartics, and other remedies entering into the so-called antiphlogistic method of treatment. Experience has abundantly shown that these measures cannot be relied upon for the arrest of this, more than of other inflammations. Admitting that they sometimes succeed, the probability of success is not sufficient to warrant their employment under circumstances which will be likely to render their operation hurtful should they not prove successful. Full doses of quinia, that is, from 20 to 40 grains, given either at once or within eight or ten hours, may arrest the disease. This statement is based on my own experience, as well as on the testimony of others. If a patient be seen in the first stage, an effort should be made to render the disease abortive by means of this remedy, inasmuch as it does no harm, aside from the annoyance of cinchonism, if it do not succeed; on the contrary, a favorable influence upon the course of the disease is produced, either by its antipyretic effect or in other ways, when it fails as an abortive remedy. The disease sometimes aborts spontaneously, that is, without treatment. A few instances have fallen under my observation. The probability, however, of the abortion occurring spontaneously is so slight that if in several cases it follow treatment employed for that end, it may fairly be considered as a successful result thereof. Rational objects of treatment exclusive of that employed for an arrest of the disease, in the first stage, are to lessen the intensity of the inflammation, to lower the temperature of the body, to relieve pain, and to promote toleration of the disease.

As regards bloodletting, irrespective of its employment as an abortive measure, the reader is referred to the general considerations presented in Chapter II.

Part II. (*vide* page 133 *et seq.*). It is admissible in certain cases as a palliative, and, perhaps, to some extent, a curative measure, in view of the promptness of its operation. The circumstances which warrant its employment are: high fever, the pulse more or less resisting compression, in other words, arterial tension, and a robust constitution. It is contra-indicated whenever the fever is not high, when the pulse is frequent and weak, and if the patient be anæmic or have a feeble constitution. The relief of pain and embarrassment of breathing by bloodletting is often immediate and marked. The efficiency of this measure as a palliative is due in part to its effect on the general circulation, and to the diminution of the functional labor of the lungs; but the relief may be in part explained by the effect in diminishing congestion of the portions of the pulmonary organs not inflamed (the collateral fluxion of Virchow), and also by the effect in lessening the accumulation of blood in the cavities of the right side of the heart. In most of the cases, however, in which the same ends can be secured by other means than bloodletting, the former are to be preferred. These consist of depletion by saline purgatives, and sedative remedies. After the operation of a saline purgative, if the skin be hot and the pulse frequent, tartar-emetic or some antimonial preparation may be given as a nauseant sedative; but the doses should not be carried to the extent of producing marked or distressing nausea. The veratrum viride may be given under the same restriction. In this country not a few practitioners regard this remedy as possessing notable curative as well as palliative efficiency. These remedies are contra-indicated by feebleness or a tendency to depression. Aconite is an effective sedative remedy, and is to be preferred to the sedatives just named whenever it be desirable to avoid the depressing effects of the latter. Opium may be given with propriety and advantage in the first stage, in doses sufficient to relieve the pain and tranquillize the system. Blisters are injudicious, but dry cups, sinapisms, or stimulating liniments may be employed. Stupes, or warm fomentations, applied to the chest, are useful. In many cases, a saline purgative followed by some form of opium, the latter continued at intervals, together with soothing applications to the chest, will meet the indications pertaining to the first stage. German authors extol cold applications over the part of the chest corresponding to the affected portion of the lung, by means of either napkins which have been dipped in cold water, and which are to be renewed every five minutes, or the ice-bag. It is stated that, after a few hours, patients are sensible of relief; and often both the respiration and the pulse become less frequent. Not infrequently, the temperature of the body is notably reduced. In some cases, however, patients complain of the application, and, if so, it should not be continued. It by no means follows that because warm applications are useful, the application of cold is not also useful, or *vice versâ;* each may have a favorable effect, the *modus operandi* of each differing from that of the other. Warm applications soothe and act as revulsives; the application of cold diminishes the determination of blood to the part, and relieves pain by obtunding the sensibility.

If the fever be high as denoted by a temperature of 103° or more, antipyretic measures are indicated, as in the diseases which are generally recognized as essential fevers. These measures are the employment of cold for the direct abstraction of heat from the body, and the administration of quinine in full doses, the latter antagonizing an excessive production of heat. Cold may be employed by means of the bath, the wet sheet, or sponging the body. Of these different modes, the two latter are less inconvenient both for the patient and others than the first, and the last mode will in most instances suffice. The object is to reduce the temperature to as near the normal maximum as practicable. Whenever, after this object is effected, the temperature rises, cold is to be again applied. It is desirable that the employment of these measures

be under the personal direction of the physician or an experienced assistant. An alcoholic stimulant should be given whenever the bath, the wet sheet, or sponging is employed. My own practical knowledge of these measures in this disease is limited, but, as far as it goes, it is confirmatory of their safety and usefulness. They are opposed by existing popular notions; hence, in private practice, patients submit with reluctance at first, and the physician incurs a risk of being blamed if the cases do not do well. These difficulties are not in the way of the use of quinia and other antipyretic drugs. Quinia is the most efficient of these. It should be given in the same way as with reference to an abortion of the disease. This remedy may suffice for the antipyretic object, rendering the cold-water treatment unnecessary, and it may be conjoined with the latter. Exposing the surface of the body to cool or cold air, is not without considerable antipyretic effect, and is unattended by any risk, although, from prevalent ideas, it seems hazardous in the minds of most persons. The axiom that patients with fever do not "take cold," is one which it is extremely desirable should become popularized. Popular apprehensions on this score often stand in the way of proper ventilation in cases of disease.

The treatment in the second stage has reference to the promotion of resolution, palliation of symptoms, and supporting the powers of the system. Blood-letting in this stage is not admissible, and depletion by means of salines is not called for. It is not an object to divert the blood from the solidified lung, for the exudation has already deprived it of blood; and the amount of exudation involves the withdrawal from the blood of a pound or more of solid matter, even when the inflammation is limited to a single lobe. Hyperæmia of the lung on the unaffected side (collateral fluxion) with œdema, occurs less often, as it seems to me, than has been supposed. It is indicated by increased frequency of the respirations and dyspnœa, accompanied by the development of fine, moist râles over the unaffected side. The application of a considerable number of dry cups over the chest, is the most effectual measure for relief. Experience has shown the inutility of remedies formerly employed as sorbefacients, namely, tartar emetic in large doses and mercury.

Repeated applications of the tincture of iodine will secure a sufficient amount of counter-irritation, if any be desirable. Blisters are not advisable on account of the general disturbance which they are apt to occasion, and their interference with physical examinations of the chest. If pain and soreness continue in this stage, stupes with warm water only, or with some stimulating liquid, as the liniment of turpentine, will afford relief. The latter will not be required if the tincture of iodine have been applied.

Opium is a valuable remedy in the second as in the first stage. It is indicated, not only by the continuance of pain, but by vigilance, restlessness, and symptoms denoting constitutional disturbance. I have repeatedly observed a rapid and notable diminution of the frequency of the pulse and of the respirations, with refreshing sleep and a condition of comfort, to follow full doses of opium. This remedy has the advantage of not doing harm if it fail to do the good which we expect from it. The free use of opium does not delay the commencement nor retard the progress of resolution. An accumulation of mucous secretion in the bronchial tubes contra-indicates the use of opium in full doses.

Remedies to promote expectoration, as a rule, are not indicated. The use of remedies of this class is based on the erroneous idea that the matter of exudation is expectorated. Clinical observation shows that the removal of this matter may go on with great rapidity without any expectoration. The expectoration in the second stage of the disease is due to bronchitis limited to the affected lobe or lobes. The mucous products rarely accumulate in the bronchial tubes to an extent to occasion inconvenience, except as a conse-

quence of a degree of exhaustion sufficient to render the muscular power inadequate to efficient efforts of expectoration; and, under these circumstances, expectorant remedies will not afford relief.

Sedative remedies, such as aconite and the veratrum viride, are admissible in this stage, if there be considerable or high fever, without a tendency to asthenia. They should be cautiously given, so as not to incur risk of constitutional disturbance or depression. A high temperature in this, as in the first stage, calls for antipyretic treatment, and the same measures may be employed. These measures are indicated whenever the thermometer shows a temperature at or above 103°.

To support the powers of life is the leading general indication in the second stage. Resolution will be sure to begin and continue if the life of the patient be sufficiently prolonged. The danger is generally, not from the amount or persistence of the solidification of lung, but from failure of the vital powers before the resolution takes place. This disease belongs among those distinguished as self-limited; if uncomplicated and not attended by accidents, it runs a definite career ending in restoration provided the powers of life hold out. These considerations, together with the results of clinical experience, enforce the importance of the supporting treatment.

The indication for supporting measures, as regards urgency, varies much in different cases. In general terms, it is urgent in proportion to the danger from asthenia. It should govern the treatment in cases sometimes characterized as asthenic, and whenever there are grounds for distrust of the adequateness of the vital powers to carry the patient safely through the disease. It is a serious mistake to defer supporting measures until the symptoms denote imminent danger from failure of the powers of life. If deferred so long, they will probably be too late. The observing and skilful practitioner will foresee and endeavor to forestall a degree of prostration attended with imminent danger. The constitution of the patient, his previous health, and his habits, are to be taken into account in judging early of the ability to sustain the disease. Other things being equal, in a warm climate, patients are less able to sustain the disease than in cold or temperate climates; supporting treatment, therefore, is oftener and earlier called for in the former than in the latter. In cases which are distinguished as asthenic and typhoid, the reliance for successful management must be on supporting measures. These views are the more to be impressed because it is undoubtedly true that, until lately, the minds of medical men have been so much occupied with the means of subduing inflammation, as to overlook the fact that means employed for this end, not only often conflict with those which are more important for recovery, but may be positively injurious, if not, indeed, destructive to life. The attention has been directed too much to the disease and too little to the patient.

The supporting treatment embraces tonic remedies, alcoholics, and nutritious diet. Of tonic remedies, quinia is to be preferred. Alcoholics form an essential part of the supporting treatment, as in all other diseases whenever the object is to keep the patient alive until the disease has reached the end of its career and advanced into the stage of resolution. The principle is the same as in other essential fevers; and here, as in the management of the latter, alcoholics are indicated to an extent commensurate with the danger from failure of the vital powers. In certain cases of pneumonitis, as in typhus or typhoid fever, and other diseases, there is often a remarkable tolerance of alcohol, and the only guide, as regards quantity, is the effect as manifested by the symptoms. No abstract rules can be laid down, applicable to all cases, but careful observation must furnish the rule proper to each individual case. Here, too, as in the continued fevers, because alcoholics are vastly important in some cases, it is not to be inferred that they are invari-

ably indicated, nor that they can never do harm; on the contrary, if pushed to an injudicious extreme, they are potent for evil, as they are potent for good when judiciously used.

As regards the circumstances under which the use of alcoholics is to be commenced, they are always indicated as soon as evidence appears of any tendency to failure of the powers of life. And of this, the action of the heart, as represented by the pulse, is the best criterion. Feebleness, great frequency, and a pulse vibratory or thrilling but compressible, denoting increased activity but diminished power of the ventricular contractions—these are the characters which indicate supporting measures, of which alcoholics are an essential part. Given at first in small or moderate doses, the effect is to be watched, and the quantity increased in proportion to the urgency of the indication. The habits of the patient, as regards the habitual use of alcoholic drinks, are of course to be taken into account. Whenever the question arises, in the management of a case, whether alcoholics are advisable or not, it should be borne in mind that to begin earlier than they are required, is far preferable to subsequent delay; for with proper care they can be suspended without any injury having been done, whereas the time lost by beginning too late cannot be regained.

Alimentation is an essential part of the supporting treatment. It is as important to nourish patients affected with pneumonitis as those affected with any febrile or other disease, whenever there is danger from failure of the vital powers. The statement that patients with pneumonitis should be encouraged to take nutritious food during the whole course of the disease, is based on considerable experience, and alimentation should enter into the treatment in proportion as the symptoms denote a tendency to asthenia. Milk with farinaceous substances, and animal broths, should form the diet, thus combining a proper variety of alimentary principles. The desires and taste of the patient may generally be trusted.

These remarks on the supporting treatment are not specially applicable to pneumonitis, but apply alike to cases of any disease, the gravity or danger of which is manifested by symptoms denoting failure of the vital powers, and they will be referred to in connection with the treatment of other affections. As applied to pneumonitis, they relate chiefly to cases in which this disease is rendered grave or dangerous either by the extent of lung involved, or by coexisting affections. It will be borne in mind that in a large proportion of the cases in which the disease is limited to a single lobe and disconnected from other affections, there is little or no intrinsic tendency to a fatal termination. In such cases no active treatment is required, either with a view to lessen the intensity of inflammation or to support the powers of the system; patients pass through the disease satisfactorily under simple palliative measures. I have treated many cases simply with attention to hygiene. It by no means follows that, because this disease exists, remedies are to be employed; they are to be employed only when there are indications calling for therapeutical interference.

In cases of pneumonitis associated with intermittent fever, quinia should be given promptly and in efficient doses. The paroxysms should be arrested as speedily as possible; the patient may be placed in great danger by their repetition. In a malarial region, or if the patient have been subject to intermittent fever, it is judicious to forestall the possible development of the latter affection by moderate doses of quinia. The malarial cachexia impairs the power of resisting the disease; hence, it is more likely to prove fatal in malarial regions, even when uncomplicated with intermittent fever.

Cases of pneumonitis complicated with delirium tremens call for the pretty free use of opium, together with alcoholics and a nutritious diet. Delirium and vigilance, if protracted, are likely to lead to a fatal termination. Peri-

carditis, as a complication, adds greatly to the gravity and the danger; but, by perseverance in the judicious employment of supporting measures, the patient may be carried safely through this combination of diseases. The occurrence of gangrene furnishes an additional indication for support. Pneumonitis occurring in connection with the continued or the eruptive fevers, generally gives rise to the indications for supporting treatment.

During the progress of resolution, the principles of treatment which have just been presented are applicable until the improvement in the local and general symptoms, in connection with the physical signs, denote convalescence. When convalescence is established, as already stated, there is no danger of a renewed attack. There is, therefore, no need of extreme precautions in order to prevent a liability to relapse. Experience shows that a solid, substantial diet may be entered upon as soon as the patient is fairly on the road to recovery, and that the recovery is more rapid than if the appetite be too much restrained. As a rule, ordinary wholesome, digestible articles of food may be allowed when they are desired by the patient. Permitting or encouraging the patient to sit up will be found not to retard recovery, but, on the other hand, apparently to hasten the progress of resolution. Early going out of doors is not objectionable.

If the disease proceed to the suppurative stage, purulent matter being either infiltrated or forming abscesses, the prognosis is extremely unfavorable, but perseverance in the employment of supporting measures is sometimes successful. It may be added, that timely and efficient support probably affords the best security against suppuration which happily is extremely rare.

I have for several years advised the carbonate or muriate of ammonia during the progress of the disease with a view to prevent cardiac thrombosis. Of course, it is difficult to obtain clinical proof of the protective efficacy of this or any other remedy against that accident. There can be no objection to the use of this remedy on therapeutical grounds, since it does not in any manner affect unfavorably the progress of the disease. Dr. A. Patton, of Indiana, in a paper advocating the free use of this remedy throughout the disease, that is, from 5 to 10 grains every three hours, states that, of 96 cases in which this constituted all the medicinal treatment, in only two cases was the disease fatal.[1] It is probable that digitalis, given with a view to increase the power of the heart's action, is useful in preventing heart-clot. This remedy has seemed to me often signally useful when the action of the heart is feeble or irregular; and also to be of use, as a nervous sedative, when delirium and vigilance are prominent symptoms.

Acute pneumonitis, the solidification extending over an entire lobe, sometimes involving a second lobe, and presenting after death the anatomical characters which have been described as belonging to this disease in the adult, occurs in young children, although infrequently as compared with its occurrence after this period of life. It is a much graver disease in young children than in adults, proving fatal in a large proportion of cases. From the absence of the subjective symptoms, and the difficulty of obtaining physical signs, the diagnosis is less easy, and the disease is not infrequently overlooked.

The attack is sometimes ushered in by a convulsion. This may mislead by directing attention to the head. Dulness, drowsiness, or stupor sometimes accompanies the progress of the disease, and these symptoms may mislead in the same way, if the symptoms referable to the chest be not marked. The expectoration, being swallowed, cannot be observed in young children. As

[1] Am. Journ. Med. Sci., Oct. 1870. Of 207 cases treated chiefly with this remedy, by Dr. J. P. Thomas, only 3 were fatal. *Vide* Virginia Medical Monthly, April, 1880.

regards local symptoms, the disease may be latent in the child, as it frequently is in the adult. But, in a certain proportion of cases, the existence of sharp pleuritic pain is manifested by the expression, and, also, by the cry in acts of coughing, or whenever a deep inspiration is taken. A diagnostic symptom, of frequent occurrence, is a moaning or grunting sound with the expiratory act. Attention to this symptom is especially important, as it points very strongly to the existence of pneumonitis. Increased frequency of the respirations and dilatation of the nostrils show the existence of some pulmonary affection compromising the respiratory function. The respirations, in some cases, are very frequent, numbering 40, 50, 60, and sometimes even many more per minute. One or both cheeks may present a circumscribed flush. If the progress of the disease be unfavorable, lividity of the prolabia and face becomes marked; more or less acceleration of the pulse occurs, and the frequency, in some cases, is very great, amounting to from 150 to 200 per minute.

When the existence of some acute affection of the chest is declared by the symptoms, the differential diagnosis lies between primary pleuritis, capillary bronchitis, the so-called lobular or broncho-pneumonitis, and lobar pneumonitis. The first of these affections being extremely rare under five years of age, the problem is usually to differentiate the latter from the two other affections. In solving this problem, the physical signs are to be relied upon, and the reliance is also upon these for the diagnosis in cases in which the symptoms denoting an acute thoracic affection are not marked. The physical signs are generally available, with care and patience, notwithstanding the difficulty of exploring the chest in the young child.

The crepitant râle is oftener wanting in pneumonitis affecting the child than the adult, but it is present in a certain proportion of cases, and is, of course, to be sought after. This sign belongs exclusively to pneumonitis, whereas the subcrepitant râle belongs to capillary bronchitis. If there be doubt as regards the discrimination between the crepitant and subcrepitant râle, it is to be borne in mind that capillary bronchitis is a bilateral disease, and the râle will be present in both sides; whereas, in the great majority of cases, pneumonitis in the child as in the adult is unilateral, and the râle will be limited accordingly to one side. Dulness on percussion is readily determinable in the child, and this is an important point in the differential diagnosis. Bronchial respiration and bronchophony may generally be obtained in the child by perseverance in auscultation, the cry answering for the voice. These signs do not belong to capillary bronchitis, and are rarely present in lobular pneumonitis. In short, the diagnosis is to be based on the same signs as in the adult, but patient efforts may be requisite to obtain them. As regards primary pleuritis, the signs denoting effusion are available in the child as well as in the adult, and their absence warrants the exclusion of that affection.

The treatment of acute lobar pneumonitis in children involves the same principles as the treatment of the disease in adults, with those modifications which therapeutical measures require in their application to infantile life. It is questionable whether bloodletting be ever advisable in young children, even when the diagnosis is clear in the first stage of the disease. As a rule, this measure is not to be employed, and the exceptions to the rule, if there be any, are few; depletion by salines may take its place. Antimonial preparations, if given at all, are to be prescribed with great caution, and, in general, other and less depressing nauseant sedatives are to be preferred. The veratrum viride, if given, should be prescribed in small doses, and its effects very carefully watched. Aconite, in children as well as adults, is a useful sedative in this affection. Blisters should not be employed. A sinapism or turpentine stupes may be applied to the chest, followed by a poultice or the water-dress-

ing. Particular attention should be given to the latter, in order to see that either the entire chest or the whole of the affected side is covered with several thicknesses of flannel and a layer of oiled muslin. The spongio-piline is a good substitute for the poultice or water-dressing. Opium need not be withheld, but must be given with circumspection. Finally, as much depends, in severe cases, in the child as in the adult, upon the early, judicious, and persistent employment of supporting measures. In children, as in adults, under certain circumstances, there is a remarkable tolerance of alcoholics. I have notes of the case of a child of a medical friend (age fourteen months), presenting the utmost gravity of symptoms, the pulse 200 and the respiration 120 per minute, in which brandy was increased to at least an ounce hourly, and, under this amount, the pulse fell rapidly to 124, and the respiration to 50 per minute, the carbonate of ammonia and a little morphia constituting the additional treatment. Recovery took place. This case is cited in illustration of the extent to which, in some cases, the employment of alcoholics may be carried. It does not follow that they are to be generally employed excessively or largely. The same rules are to be observed in their use in children as in adults, with a view, on the one hand, to secure the benefits of alcoholics, and, on the other hand, to avoid the evils of their over-use.

Pathological Character of Acute Lobar Pneumonitis.—I have made the above heading the last in treating of this disease, for the reason that, had it been introduced in the usual order, an anticipation of facts pertaining to the etiology and treatment would have been necessary. The view now taken of the pathological character of the disease differs from that presented in the previous editions of this work, and is not generally, as yet, entertained by medical writers and practitioners.

Acute lobar pneumonitis, in the nosological systems of the present, as of past, time, is placed among the local diseases, and, in regard to certain questions, it has been regarded as the type of a purely inflammatory affection. This view of its pathological character I hold to be erroneous. The pulmonary affection is, doubtless, inflammatory; but it is the local manifestation or the anatomical characteristic of a febrile disease, sustaining to the latter a relation analogous to that which the affection of the solitary and agminated glands sustains to typhoid fever. If this doctrine be true, the proper place for the disease in the nosology is among the essential fevers. It is here retained in the class of diseases of the respiratory system simply for convenience of reference so long as its claims to be transferred to the division of general diseases are not generally recognized. The name acute lobar pneumonitis denotes only a local inflammatory disease. A more correct name is pneumonic fever (febris pneumonica), a name used by the older writers, and corresponding to the popular term "lung fever" formerly in vogue in some parts of this country.

The doctrine just stated is held by some distinguished writers of the present day. It is advocated especially by Juergensen.[1] It was enunciated in this country by Dr. Wm. H. Draper in a paper read to the New York Academy of Medicine in 1866, and published in the Bulletin of the Academy for that year. The grounds for maintaining the doctrine were embodied by me in a paper published in the Transactions of the New York State Medical Society for 1877. These grounds, concisely stated, are as follows:—

In relation to the morbid anatomy, the quantity of exudation, amounting to from one to two pounds if a single lobe be affected, and sometimes reaching four pounds if the affection embrace an entire lung; the derivation of this matter from the blood in the branches of the pulmonary artery; the removal of the

[1] Vide Ziemssen's Cyclopædia, Am. edition, vol. v., 1875.

exudation by absorption, leaving the air-vesicles intact; the extension over a lobe by degrees, the progress often being slow; the invasion successively of a second and a third lobe in a certain proportion of cases, and the laws of the disease, as regards the greater liability of the lower lobes, and of the lower lobe of the right lung—these are points which, to say the least, are suggestive of dependence on a constitutional morbid condition, the latter being essentially the disease. It is not easy to reconcile the pathological facts just stated with the doctrine that the pneumonic products are the results solely of a local inflammatory condition; and if a prior constitutional condition be essential, that condition is a fever. In some regards the anatomical characteristics of pneumonic fever bear a close analogy to those of typhoid fever.

Etiology furnishes support of the doctrine in two points of view, namely: First, the local affection is never produced by local causes; and, second, all the knowledge which we at present have of the causation is in favor of the primary action of the cause or causes being constitutional. Acute lobar pneumonitis is always developed irrespective of any extrinsic agencies acting directly upon the pulmonary organs. Agencies which it might be supposed, *a priori*, would be followed by the disease, fail to produce it. Contusions, however violent, and penetrating wounds of the chest, never give rise to acute lobar pneumonia. It does not follow the diffusion of pus from empyema or an hepatic abscess. Circumscribed gangrene of lung does not lead to it. In bronchitis affecting the small bronchial tubes, the inflammation may extend to certain lobules, producing local effects, however, quite different from the anatomical characters of lobar pneumonitis, the latter never occurring, nor does it ever occur as a sequence of acute pleurisy. Juergensen does not make too strong an assertion when he says that "croupous pneumonia can no more be produced by the excitants of inflammation than can the characteristic intestinal lesions of typhoid fever.

The disease, as is well known, is not infrequently an intercurrent affection in the course of other essential fevers, namely, typhus and typhoid fever, measles, diphtheria, etc. In these instances the determining cause must be constitutional, and yet, as the disease is only an occasional complication, the determining cause involves something which does not necessarily pertain to these fevers. This something, it is reasonable to conclude, is pneumonic fever. Hence, it follows that pneumonic fever may be associated with other febrile diseases. The blending of different fevers may be considered at the present time as a well-established pathological doctrine. An example with which all are familiar is the typho-malarial fever.

It is evidence that it is a constitutional or general disease (and if so, it must be an essential fever) if it involve a specific causation. A specific cause, with our present knowledge, is not demonstrable; but this confession is to be made respecting other essential fevers—for example, typhoid fever. A conclusion can only be reached by the logical force of facts. Certain of these facts belong to the morbid anatomy and to the clinical history. Etiological proof of a specific causation is afforded by the prevalence of the disease at certain seasons of the year, namely, the vernal months in this climate, and its comparatively infrequent occurrence at other seasons. Proof is also afforded by the fact that the disease is far more prevalent in some climates than in others. In our country it is vastly more frequent in the Southern than in the Northern States. Still further proof is afforded by the fact that, at certain times and in certain situations in the South, it has been known to prevail to an extent entitling it to be called an endemic. To these facts it is to be added that at different periods and places the variations of the disease as regards its phenomena and the rate of fatality, constitute a point of distinction from purely inflammatory affections, and affiliate it with the essential fevers.

Passing to the clinical history, the grounds are hardly less substantial than those furnished by the etiology of the disease.

The chill, which is usually the first symptomatic event, is more pronounced than in the history of any purely local inflammatory affection. It is often as marked as in the cold stage of a paroxysm of intermittent fever. The fever which follows, quickly rises and often in a few hours becomes intense. It is not uncommon for the temperature of the body to be five or six degrees above the normal limit in from four to twelve hours after the attack. Now, this cannot be a symptomatic fever, for within these periods, and often for two or three days, the pneumonic inflammation is so limited as not to furnish the distinctive and easily determined physical signs of the local affection. Contrast, as respects the intensity of the fever at the outset, pneumonic fever with acute pleurisy. During the course of the disease, the fever, as represented by temperature and other symptoms, has no uniformity of relation with the pulmonary affection. What is true of typhoid fever, in respect of the influence of the intestinal lesions upon the febrile phenomena, is equally true of this disease. As in other fevers, enlargement of the spleen and albuminuria are frequent in this disease.

As in typhoid fever, defervescence is not determined by conditions which relate to the local affection. Defervescence sometimes begins and ends within twelve hours, or even less, and during this time the physical signs may show that no very marked change has taken place in the pulmonary organs. The disease, like typhoid fever, ends from self-limitation—that is, it ends when the disease has finished its career. The duration of this career varies considerably, it is true, in different cases, but it is, nevertheless, self-limited. It is not uncommon for the career of the fever to end when there is much to be done in the way of resolution before the restoration of the normal pulmonary condition is complete.

The analogy to typhoid fever, which in several points of view is apparent, is further shown by the frequent occurrence of what are known as typhoid symptoms. It is true these symptoms occur in various diseases; but I am warranted in saying that they occur in this disease far more frequently than in any local affection or in any disease other than typhus and typhoid fever. They certainly cannot be attributed to the interruption of the respiratory function, for they are rarely frequent in other affections which occasion great disturbance of this function—for example, pleuritis and capillary bronchitis. They are undoubtedly due to the fever, irrespective of the pulmonary affection; and, in this point of view, the disease resembles typhoid fever.

It differs from local inflammatory diseases, and resembles most of the essential fevers, in the fact that, when the career of the disease has ended, there is no immediate tendency to a relapse. In a large number ot cases which I have recorded, in not a single instance was a relapse noted; and I cannot recall an instance in my unrecorded experience. Is there not in this fact solid ground for the doctrine that the disease is an essential fever? Another striking fact may be mentioned in this connection, namely, the pulmonary affection never persists in a chronic form. The forms of chronic pneumonitis, that is, ordinary and fibroid phthisis, are anatomically distinct from lobar pneumonitis; nor does clinical experience substantiate the opinion held by some that phthisis is a sequel of acute pneumonitis. It may be asserted, as of typhoid fever, that if death do not take place from either the disease, its complications, or its accidents, recovery follows without any risk of the persistence of the local affection in a chronic form.

The therapeutic influence of certain remedies and of antipyretic measures furnishes ground for the doctrine that acute lobar pneumonia is not purely an inflammatory affection.

As long ago as in 1861 I was led, by the results of the analysis of a considerable number of cases in which the sulphate of quinia was given to the extent of only 15 grains daily, to the conclusion that this remedy exerted a marked curative influence upon the disease. I can now bear testimony to the fact that, given in larger doses, namely, from 20 to 40 grains daily, this remedy, in a certain proportion of cases, renders the disease abortive, and that, when this result does not follow, the disease is often favorably modified in a greater degree than by smaller doses. Now, whatever efficacy belongs to these remedies, proceeds evidently, not from any direct effect upon the pulmonary affection, but from a controlling influence over the pyrexia; thus sustaining the doctrine that the disease is an essential fever. Juergensen, Liebermeister and other German writers claim, as a conclusion based on clinical experience, that the reduction of the high temperature of the body by cold baths, employed as in cases of typhoid fever, lessens the severity of the disease and the rate of fatality from it. Accepting this conclusion, it is further evidence of the correctness of the doctrine.

Assuming that there are grounds sufficient for adding to the list of essential fevers *febris pneumonica*, or pneumonic fever, we may define the disease as follows:—

It is a fever characterized anatomically by an abundant exudative deposit in the air-vesicles of a single lobe, or of two, and sometimes three, lobes of the lungs, with, in general, circumscribed bronchitis and dry pleurisy. It is a fever which rapidly reaches its maximum intensity, and has a short career, the duration averaging about eleven days. It proves fatal chiefly in consequence of associated diseases, complications, or accidents, and the mode of dying is by asthenia. It is non-communicable, and depends on a cause, or on causes, specific in character, the nature of which is at present unknown, but having relations to season and climate. It sometimes aborts spontaneously; and it is in some instances arrested by remedies. If not arrested, it may be favorably modified, its duration abridged, and the danger to life diminished by treatment addressed, not to the pulmonary affection, but to the fever.

Circumscribed Acute Pneumonitis.

This term applies to cases of acute pneumonitis in which the anatomical appearances resemble those in the lobar form, the pulmonary affection being circumscribed. As a primary disease, this circumscribed form is very infrequent, and yet, perhaps, not as rare as is generally supposed, for, if much circumscribed, the affection may be readily overlooked, since the physical signs may escape detection, and it very rarely terminates fatally.

The pneumonitis is circumscribed, that is, it does not extend over an entire lobe, when the so-called acute lobar pneumonitis, or pneumonic fever, aborts either spontaneously or under abortive treatment. The cases of primary circumscribed acute pneumonitis occasionally observed, are perhaps cases of pneumonic fever, in which the disease ceases before the inflammation has extended over a lobe.

Circumscribed pneumonitis with fibrinous (croupous) exudation, is more frequently a secondary affection; thus it is an occasional concomitant of phthisis. More or less of the lobules in proximity to the phthisical products become solidified by a deposit resembling that in acute lobar pneumonitis. An examination of the chest may disclose a crepitant râle within a limited area, and this râle is to be reckoned one of the accessory signs of phthisis. Following this râle, or without its having been observed, the physical signs show a solidification greater in degree and extent than had been found on previous examinations. After a short time, resolution of this secondary pneumonitis

takes place, and then the signs represent only the antecedent phthisical affection. Cases exemplifying what has just been stated have repeatedly come under my observation. The occurrence of such attacks of circumscribed pneumonitis will account for changes as regards the physical signs, which, if not thus interpreted, are inconsistent with the anatomical history of phthisis. These and similar cases of secondary fibrinous (croupous) pneumonitis resemble lobular pneumonitis in being circumscribed, but in other macroscopical, and in the microscopical, appearances, they have more similarity to the lobar form.

Embolic Pneumonitis. Pyæmic Abscesses in the Lungs.

Embolism has been considered in the first part of this work, *vide* page 30. Pulmonary emboli are derived from the right side of the heart or from the systemic veins. In the former case they originate most frequently from thrombi in the appendix auriculæ or in the ventricular apex. In the latter case, the emboli are derived from thrombi within the veins. An important distinction is based upon the action of emboli as simply mechanical plugs, or as bringing with them matter which excites inflammation by its irritating properties. The latter are distinguished as infectious emboli.

The emboli which act only mechanically, give rise to local congestion and hemorrhagic infarctions. These effects of embolism will be considered in connection with extravasation of blood within the lungs (Pneumorrhagia, Pulmonary Apoplexy). They will be referred to also in connection with pulmonary gangrene. Pneumonitis may not accompany these effects of embolism, except to a limited extent around the spaces in which the infarctions are seated.

Infectious emboli, on the other hand, becoming lodged in branches of the pulmonary artery, give rise to abscesses. These are sometimes called metastatic abscesses, the pus being formerly supposed to have been transported from some part of the body and deposited within the lungs. They are called pyæmic abscesses because they are incident to pyæmia.

The source of the emboli is usually to be sought in thrombi formed in veins leading from some centre of infection, such as external wounds, inflammation of the uterine sinuses in puerperal women, bed-sores, abscess of the middle or external ear and of other situations, ulcerative endocarditis, etc. The embolus brings with it some poison which acts as an intense inflammatory irritant. It is not always possible to find the primary thrombus, nor can the embolus in all cases be demonstrated. It is probable that the poison may be carried by the blood-current in a finely molecular form or in a dissolved state.

Metastatic pulmonary abscesses vary in number from one to several hundred, and in size from a pin's head to those involving an entire lobe. They may or may not be accompanied by the mechanical effects of emboli, that is, by hemorrhagic infarctions. There is nothing peculiar about the anatomical appearances of the abscess; it is a cavity filled with pus, which is in some cases fetid; the surrounding lung tissue may be the seat of circumscribed pneumonitis, or it may be simply œdematous and congested or hemorrhagic.

There is often a coincident general pleuritis, sometimes with pus in the pleural cavity. The abscess may rupture into the pleural cavity. The termination is usually fatal.

In cases of pyæmia, the occurrence of embolic pneumonitis is denoted by the following symptoms: Cough and expectoration, the latter containing blood, if, as may be the fact, infarction and inflammation are combined; increase of the frequency of respiration out of proportion to the heart's action or the pulse, and pleuritic pain from circumscribed pleuritis. With these local symptoms,

there may be more or less dyspnœa. It is impossible to disconnect the general symptoms, fever, chills, etc., which are symptomatic of the pulmonary affection, from those which belong to the clinical history of pyæmia. By the physical exploration of the chest, lobar pneumonitis is excluded. It is rare that the different foci of inflammation involve sufficient areas to give rise to the signs of solidification. Moist bronchial râles may be found at different points. Direct physical evidence of pulmonary affection is often wanting, and the diagnosis must be based chiefly on the local symptoms taken in connection with the existence of pyæmia.

Pyæmic abscesses doubtless contribute to the fatal termination in cases of pyæmia.

The treatment, as far as it concerns the pulmonary affection, embraces only palliative measures.

Brown or Pigment Induration of the Lungs.

The lesion thus entitled and described by Virchow, in 1847, is referable to the long-continued passive congestion incident to valvular disease of the left side of the heart, particularly to obstruction and to regurgitation at the mitral orifice. Lungs thus affected do not collapse on opening the chest as much as when they are healthy. They are heavy, inelastic, dry, crepitating on pressure but little, of a leathery consistence; and they have a peculiar reddish-brown, yellow, or salmon color. On section, reddish or brown spots may be seen, due to ecchymoses. The microscope shows that the essential morbid condition is a dilatation of the pulmonary capillaries, loops of which often project far into the alveoli and partially obstruct their lumina. The air-cells are still further obstructed by the presence of large epithelial cells containing yellow or brown pigment, which cells may accumulate in sufficient number to fill the alveoli. Pigment is also found within the capillary vessels, in the capillary walls, and in the interstitial tissue, both free and inclosed in cells. The pigment is derived from red blood-corpuscles which escape through the capillary walls by diapedesis, in part also by rupture of the walls. The walls of the air-cells and the interstitial tissue often appear hypertrophied. Rindfleisch describes also an hypertrophy of the smooth muscle-fibres of the pulmonary parenchyma in this affection.

The symptoms denoting the lesion are not definite, but it must increase the dyspnœa which is connected more directly with the cardiac disease.

Pneumonokoniosis, Anthracosis, Siderosis, etc.

Under the generic name pneumonokoniosis, proposed by Zenker, are included the various affections of the lung produced by the inhalation of dust-like particles. A considerable number of such inhalation-diseases is already known. The one longest recognized is the lesion caused by the inhalation of coal-dust. A moderate amount of black coal-pigment is found in the lungs of all adults, more especially of those living in cities. But in the lungs of those who have been exposed for a long time to a dense atmosphere of coal-dust, the carbon-particles accumulate to such an extent as to cause a lesion called *anthracosis* of the lungs. This lesion is produced especially in coal-miners. The particles of coal are carried by the current of inspired air into the air-vesicles or alveoli. Thence, either free or inclosed in cells, which are probably emigrated white blood-corpuscles, they make their way into the alveolar septa, and are still further conveyed through the lymph-spaces and lymph-vessels into the interlobular and peribronchial connective tissue. Some of the particles reach the bronchial glands, and exceptionally may even be carried to the cervical or abdominal

lymphatic glands. The lungs and bronchial glands are black; the microscope shows the coal-pigment to be chiefly in the interlobular connective tissue and in the bronchial glands, but it is also present inside of cells in the alveoli and in the walls of the air-vesicles. Extensive anthracosis may exist without any other changes in the lung than chronic bronchitis and the presence of some large cells containing pigment in the alveoli. Frequently, however, it is combined with other chronic inflammatory changes, particularly with chronic interstitial pneumonitis. Dense fibrous bands and nodules deeply pigmented are found. The walls of the alveoli are thick, and their lumina obstructed or even obliterated by the new growth of fibrous tissue. Firm pleuritic adhesions are present. Combined with these chronic interstitial changes, bronchiectasic and ulcerative cavities may be present. Anthracosic lungs are also predisposed to the development of chronic pulmonary tuberculosis, in which case tubercles and tuberculous pneumonitis will be found. To pulmonary anthracosis with chronic interstitial inflammation with or without the presence of tubercles, the name coal-miner's phthisis is applied. The coal particles, when of a sufficient size, can be recognized as such under the microscope; often, however, they are not to be distinguished from melanotic pigment derived from the blood. The coal particles are often present in the expectoration of those affected with anthracosis pulmonum.

The term *siderosis pulmonum* denotes the accumulation in the pulmonary structures of the oxide of iron. This oxide forms a very fine, brownish-red dust. It is inhaled by workmen employed in dyeing, polishing mirrors, and other mechanical arts in which it is used. Accumulating in the lungs it causes a reddish pigmentation. Its morbid effects were first studied by Zenker.[1] They are essentially the same as in anthracosis, the color being red instead of black.

Chalicosis pulmonum is the name given to the pulmonary changes induced by the inhalation of stone-dust. It is also called stone-cutter's phthisis. The chemical examination of these lungs shows the presence of an excess of silica. The changes are similar to those of anthracosis and of siderosis, with the exception of the greater disposition to the formation of nodules of fibrous tissue. These have a gray centre and dark periphery. The foreign particles can be recognized microscopically, but not so readily as in the previous affections.

Various other forms of pneumonokoniosis have been described, such as those due to the inhalation of particles of tobacco, of cotton, of grain, of various metals, etc.

The clinical history of the different varieties of pneumonokoniosis is that of bronchitis which is generally chronic, together with, in a certain number of cases, fibroid phthisis. The production of broncho-pneumonia by the inhalation of particles of grain will be noticed in treating of that affection in the next article.

The removal of the patient from the continued operation of the cause, is, of course, the first object of treatment. In other respects the indications relate to the diseases which are incident to the pneumonokoniosis.

Lobular Pneumonitis. Broncho-pneumonitis. Atelectasis.

Lobular pneumonitis is also frequently called *catarrhal pneumonia* from the fact that the exudation is chiefly cellular. This latter name, however, is inappropriate because the epithet catarrhal is only applicable to inflammations of mucous membranes, and the wall of the air-cells and alveolar passages can-

[1] Deutsches Archiv f. Klin. Med., Bd. II. p. 116.

not be considered properly a mucous membrane; and, moreover, fibrin is sometimes present in the exudation of so-called catarrhal pneumonia, as well as in that of lobar pneumonitis. The name *cellular pneumonia* employed by Virchow is also not sufficiently distinctive. The terms *broncho-pneumonitis*, implying the coincident affection of the bronchi and of the air-cells, and *lobular pneumonitis*, signifying the lobular dissemination of the inflammation, are to be preferred.

Lobular pneumonitis is a secondary affection, and almost always secondary to inflammation of the smaller bronchi. It is frequent in childhood, but rare in adults, except in the debilitated and the aged. In the new-born and in very young children it is usually preceded and accompanied by *atelectasis* or collapse of a greater or less number of pulmonary lobules (apneumatosis). Atelectasis may attend lobular pneumonitis occurring later in life, but it is a less constant accompaniment. Portions of the lung tissue in the condition of atelectasis contain no air; they are non-crepitant and sink in water. They present a bluish-red appearance through the pleura, and a more brownish-red color on cross-section. They have a smooth surface, a firm consistence, and are depressed below the level of the surrounding lung tissue. They can be inflated by blowing through the bronchi. In many cases, but not always, occlusion of the bronchi immediately connected with the atelectatic spots can be demonstrated. The most frequent source of obstruction is an accumulation of the products of inflammation in the smaller bronchi. The air-cells connected with the occluded bronchi collapse after the absorption of the contained air. Microscopical examination of the collapsed lobules shows distension of the pulmonary capillaries with blood, and the presence of granular, desquamated epithelial cells in the collapsed alveoli. Atelectasis of portions of the lungs may be a *congenital* condition in the new-born and in infants a few days or weeks old, the affected lobules having never been inflated in consequence either of weakness of the respiratory efforts, or of obstruction of the bronchi by mucus, meconium, etc. *Acquired atelectasis* is far more frequent in children than in adults. The name atelectasis is also sometimes applied to the condition called carnification of the lungs, the air having been expelled by pressure from without, as by an extensive fluid accumulation in the pleural cavity. Atelectasis of whatever form is more frequent in the lower lobes than in the upper. Single circumscribed lobules may be affected, or even a whole lobe. When there is extensive atelectasis, the remaining parenchyma of the lung is usually in the condition of vicarious vesicular emphysema.

There has been much controversy as to the relations between atelectasis and lobular pneumonitis. Former writers regarded atelectasis as congenital pneumonia, and, since the true nature of the condition has been recognized, it has usually been held that collapse of the air-cells in itself leads to the development of lobular inflammation. It is probably not correct to regard either acquired pulmonary collapse or a preservation of the fœtal state of the lungs alone as a cause of inflammation. We may consider that lobular pneumonitis occurs only when there is present within the alveoli an irritant capable of inducing inflammation. Most foreign particles, and particularly the stagnating secretion of the inflamed bronchial mucous membrane, are irritants capable of exciting bronchitis and lobular pneumonitis by entrance into the small bronchi and the air-cells, whether or not they completely obstruct the bronchi and lead to atelectasis.

The pathological changes occurring in lobular pneumonitis have been divided into the same three stages as in lobar pneumonitis, namely, first, congestion or engorgement; second, red hepatization; and, third, gray hepatization. Such a division is, however, less important and well defined in lobular than in lobar pneumonitis. In a typical case of lobular or broncho-

pneumonitis, disseminated throughout both lungs are small firm spots, varying in size from a pea to a pigeon's egg. The color may be brownish-red, reddish-gray, gray, or yellowish, and the periphery is usually darker than the centre. The surface is lustreless, smooth or slightly granular, and somewhat elevated above the surrounding lung tissue. The consolidated pulmonary substance is non-crepitant and sinks in water. When the solidified lobules are situated at the surface of the lung, the overlying pleura is coated with a delicate layer of fibrin. Usually drops of muco-pus can be squeezed out of the smaller bronchi. The microscopical examination of the solidified lobules shows the air-cells to be filled, though less distended than in lobar pnumonitis, with pus-cells, epithelial cells, and some granular matter in varying proportion. In some cases the pus-cells predominate, in other cases large granular cells with vesicular nuclei, thought to be alveolar epithelial cells. Red blood-corpuscles are usually present, but not in such number as in lobar pneumonitis. The presence of large numbers of pus and epithelial cells in the alveoli, the comparatively small number of red blood-corpuscles, and the absence of fibrin may be considered to be the characteristics of the exudation of broncho-pneumonitis as distinguished from the lobar form. Exceptionally, however, fibrillated fibrin may be found in the exudation of lobular pneumonitis, and, in fact, as far as the inflammatory products are concerned, there is every grade of transition between a typical, purely cellular exudation and the fibrino-cellular and almost hemorrhagic exudation of lobar pneumonitis. There is also great variety in the extent of lung involved in the inflammatory process. The pneumonitis may be confined to a few lobules, as, for instance, those surrounding a hemorrhagic infarction or a new growth; there may be countless nodules of consolidation scattered throughout both lungs, or even all the lobules of a lobe may become involved. In the rare cases of lobar consolidation from lobular pneumonitis, the fact that the lobules are not simultaneously, but successively, involved, gives to the surface a peculiarly variegated appearance different from that observed in lobar pneumonitis. The surface is also less granular than in the latter disease. As to the origin of the cells which fill the alveoli, it is customary to regard the pus-cells as emigrated white blood-corpuscles. Whether the alveolar epithelium plays an active part in the inflammatory process is a matter of dispute. There is no proof of the production of pus-cells from proliferating epithelial cells, and, in those cases in which the number of large epithelial-like cells in the alveoli seems greater than can be accounted for by a mere desquamation of the epithelial lining, it is not necessary to assume active proliferative changes in the epithelium, as it is abundantly proven that wandering leucocytes can become transformed into epithelioid cells.

The most frequent termination of lobular pneumonitis is in resolution. As in lobar pneumonitis, the cell elements undergo fatty degeneration, and by transudation of serum a kind of emulsion is formed capable of absorption.

It is held by most authorities that the inflammatory products of lobular pneumonitis may undergo caseous metamorphosis which leads to the development of pulmonary phthisis. In these cases, changes peculiar to phthisis and other than those of a simple lobular pneumonia will be found. The anatomical description of these changes belongs to the subject of pulmonary phthisis.

Clinical History.—Inasmuch as a bronchitis affecting both sides (bilateral) precedes and accompanies the collapse of lobules in lobular pneumonitis, the symptoms of that disease are always present. As will be seen in treating of bronchitis in a following chapter (Chapter VII.), the symptoms attributable

to the bronchial inflammation vary according to its extension into tubes of small size. In addition to cough and expectoration, increase in the frequency of the respirations, dyspnœa, and cyanosis may be accounted for by the bronchitis alone, if tubes of small size become involved (capillary bronchitis). These symptoms are more marked in proportion to the number of lobules collapsed and inflamed. The symptoms are chiefly due to the pneumonitis, if the bronchitis be limited to tubes of large or medium size.

The bronchial inflammation may be acute or subacute. The pyrexia is proportionate to the acuteness of the bronchial inflammation, and to the extent of lung affected. This will, therefore, vary considerably in different cases. The symptoms relating to the frequency and other characters of the pulse offer variations dependent on the intensity of the fever and the obstruction to the passage of blood through the pulmonary vessels. Corresponding variations in other constitutional symptoms are incident to the fever and disturbance of the circulation. It follows that broncho-pneumonitis may be a disease of great severity and danger, or it may be comparatively devoid of gravity. Some cases are characterized by notable fluctuations during the course of the disease, owing to an increase, at different periods, of the number of lobules implicated. The symptoms on successive days may fluctuate, collapsed lobules becoming inflated, or an additional number of lobules becoming affected.

Diagnosis.—The diagnosis relates to two factors, as regards the symptomatic phenomena, namely, the bronchitis and the collapsed or inflamed lobules. A third factor is the occurrence of emphysematous lobules (lobular emphysema). The physical signs denoting the bronchitis are the moist bronchial or bubbling râles, which are coarse, fine, or subcrepitant, according to the size of the tubes in which they are produced. Râles varying in coarseness or fineness may be combined. The collapsed and inflamed lobules may furnish no distinctive signs, if in the form of small nodules, disseminated, and about equal in number on the two sides. Broncho-vesicular or bronchial respiration, increased vocal resonance and bronchophony, together with dulness on percussion within a circumscribed space, on one side or on both sides, may be found wherever a sufficient number of lobules in close proximity to each other are affected so as to give rise to solidification extending over a considerable area. Lobar pneumonitis is excluded by the fact that the solidification does not extend over an entire lobe. On the other hand, the signs of solidification show something more than bronchitis, this disease alone not giving rise to these signs. If no signs of solidification be discovered, it is difficult, or impossible, to differentiate broncho-pneumonitis from bronchitis affecting tubes of small size. In severe cases, inspection shows retraction of the lower part of the chest on both sides with the acts of inspiration, and sinking in of the soft parts above the clavicles, as in cases of capillary bronchitis. Emphysematous lobules of the upper lobes will give rise to a vesiculo-tympanitic resonance on percussion.

Causation.—Age is to be regarded as the most important element in the causation. The fact that, in a very large majority of cases, the subjects are infants or children and those advanced in years, is probably to be explained by the much greater tendency in bronchial inflammation to extend to the smaller bronchi in the two extremes of life. The affection occurs not infrequently as a sequel of the eruptive fevers, rubeola, scarlatina, smallpox; also of diphtheria, and, more rarely, of the continued fevers. It may be produced in persons of any age, traumatically, by the inhalation of chlorine or other gases, of vapors, and of irritating substances of various kinds. Exposure to the latter

causes may be incident to certain occupations. Professor T. F. Rochester has lately given an account of its occurrence among workmen in "elevators," that is, buildings constructed for the removal of grain from vessels to cars and canal boats. In the city of Buffalo, during the active business season, as many as fifteen hundred workmen are employed as "shovellers" or "scoopers," in gangs of from twenty-five to fifty. These men often work continuously for a period of from thirty-six hours to six or seven days, during the night as well as in the daytime, with brief intermissions for eating and sleeping, exposed constantly, in close quarters, to the inhalation of dirt, dust, and minute particles of grain, much of the latter "bearded." Capillary bronchitis and lobular pneumonitis are developed in a considerable number, often proving fatal. The affection is called in Buffalo the "elevator pneumonia." The average duration of life among those who continue in this occupation is reckoned not to exceed five years.[1] The pneumonitis which is apt to accompany exudative laryngitis (croup) in children is a broncho-pneumonitis. Its occurrence in cases of whooping-cough is not infrequent. In the insane or the delirious, with obstructed sensibility of the air-passages, foreign particles, such as bits of food, the buccal fluids, etc., are apt to be inspired into the small bronchi and air-cells, giving rise to lobular pneumonia, which, in these cases, may be of a rather diffuse character. This is the deglutition-pneumonia (Schluck-pneumonie) of German writers.

Treatment.—The therapeutic indications have reference, first, to the bronchitis, and second, to the inflammation and the collapse of lobules. The former are the same as in cases of bronchitis irrespective of the lobular conditions, and they will be considered in a following chapter. The prompt and efficient treatment of bronchitis, especially in the young and old, is important by way of preventing the collapse and inflammation of lobules. Energetic inspirations are important in order to prevent collapse of lobules, and for the inflation of those already collapsed. For these objects, the air which the patient breathes should be cool or even cold, and the vital powers should be sustained by a nutritious stimulation and alcoholics. Juergensen's method of exciting deep inspirations by the cold affusion or a douche directed upon the nucha, may be employed. If there be hyperpyrexia, it is to be combated by the cold bath or by sponging the surface of the body, as in other diseases whenever antipyretic treatment is indicated, and by full doses of quinia. Alcoholics and digitalis are indicated by feebleness of the heart's action, as in cases of acute lobar pneumonitis. Emetics are indicated in children by accumulations in the bronchial tubes, which the patient does not remove by voluntary expectoration. The emetic selected should not produce prolonged nausea or much prostration. The hypodermic injection of apomorphia may be employed. The dorsal decubitus should not be constantly maintained; changes of position are important as preventive of collapse of lobules.

Congenital atelectasis in the newly-born is denoted by rapid, short acts of breathing, feebleness of the cry, difficulty in nursing from want of breath, and cyanosis. The absence of cough and bronchial râles suffices to exclude bronchitis. Congenital malformations of the heart are excluded by the absence of their physical signs. The respiratory murmur is feeble, especially at the lower and posterior portions of the chest. The lower part of the chest in front is retracted in the act of inspiration.

Inasmuch as the deficient expansion of the lungs is due to weakness of the respiratory acts, the strength of these should be increased by the momentary

[1] *Vide* Buffalo Medical and Surgical Journal, December, 1879.

application of cold water to the chest, exposing the body for a few moments to cold air, and exciting in various ways crying efforts. Care should be taken to free the nostrils and throat from the accumulation of mucus.

Pleurodynia and Dorso-Intercostal Neuralgia.

A brief consideration of these affections is included in this chapter, because, from similarity as regards pain, they are liable to be confounded with either acute pneumonitis or pleuritis. Prior to the employment of physical exploration, this mistake was by no means uncommon, and it is still made by those who depend on symptoms alone. The term *pleurodynia* is applied to a painful affection of the muscles entering into the composition of the thoracic walls. *Intercostal or dorso-intercostal neuralgia* denotes a neuralgic affection of the intercostal nerves.

Both affections may be characterized by pain resembling that of either acute pneumonitis or pleuritis; that is, a lancinating pain felt especially in the act of inspiration. They may be accompanied by a dry cough which is acutely painful. In cases of pleurodynia there may be pyrexia, and this may accidentally exist in cases of intercostal neuralgia. How are these affections to be discriminated from inflammation of the pleura, either primary, or occurring as a complication of inflammation of the pulmonary parenchyma?

Intercostal neuralgia, as a rule, is not accompanied by pyrexia. But this affection has a diagnostic criterion which is readily available. It consists in the existence of tenderness usually in three isolated points, namely, behind, near the dorsal vertebræ; laterally, in one, two, or three intercostal spaces, and anteriorly, in one or more intercostal spaces near the sternum or over the epigastrium. Sometimes tenderness exists in only two of these situations. The tenderness is frequently confined to a very limited space in each situation, a space perhaps small enough to be covered by the finger. On the opposite side of the vertebræ, and between the tender points in the three situations, pressure or percussion is well borne. In addition to this diagnostic test, physical exploration fails to discover the evidence of either pleuritic or parenchymatous inflammation, namely, in primary pleuritis a friction murmur and the signs denoting pleuritic effusion, and, in pneumonitis, the crepitant râle and the signs of solidification. The affection occurs much oftener on the left than on the right side. Both sides may be affected, but this is extremely rare.

Pleurodynia lacks a similar positive test, that is, the tenderness is not limited to isolated points, but is more or less diffused. The diagnosis, therefore, must rest on the exclusion of intercostal neuralgia by the absence of the evidence just stated, together with the absence of the signs of both pleuritis and pneumonitis. Pain in pleurodynia and intercostal neuralgia is more marked, as a rule, in movements of the body than in the respiratory movements, the reverse being true of the pain in pleuritis and pneumonitis. This remark applies more especially to pleurodynia. The tenderness in both affections varies, being sometimes slight and sometimes exquisitely acute.

Of the two affections, pleurodynia is much the less frequent. Before the diagnostic criterion of intercostal neuralgia had been pointed out by Bassereau and Valleix, cases of this affection were doubtless often considered as rheumatic, and hence, cases of the neuralgic affections have apparently increased of late at the expense of pleurodynia. Intercostal neuralgia is of frequent occurrence. Case are often met with both in private practice and among patients treated at hospitals and dispensaries, but more especially the latter. The poorer classes are more liable to it than those in comfortable circumstances. It occurs oftener among females than males. Persons affected are

frequently anæmic. It is apt to be developed during the progress of pulmonary phthisis. It occurs especially as a sequel of intermittent fever.

The degree of suffering from these affections varies much in different cases. They are sometimes so slight as merely to occasion annoyance, but in some cases the pain is sufficiently severe to shorten the inspirations, thus rendering the respirations frequent, as in acute pleuritis, and occasioning great distress. In the neuralgic affection, exacerbations of pain are frequently experienced. They vary greatly in different cases as regards duration, occurring sometimes as transient affections, but in some cases persisting for a long period. Pain and soreness in the chest are sometimes assumed by malingerers, but a ready proof of the reality of the affection is the diagnostic test, namely, the limitation of the tenderness to the three points on one side of the chest. This proof is reliable, unless the malingerer have had shrewdness enough to discover that this test is relied upon for the diagnosis.

The treatment of both affections embraces measures to relieve pain if it be severe or considerable. Opium may be required internally or hypodermically for this object. Local applications may suffice if the pain be slight or moderate, for example, liniments containing chloroform or aconite, or the belladonna plaster. In cases of intercostal neuralgia, quinia is an effective remedy, whether the affection be a sequel of intermittent fever or not. The quinia should be given in doses sufficient to occasion slight cinchonism, and continued in such doses for one or two weeks. If anæmia exist, this condition claims appropriate treatment. The citrate of iron and quinia or the tincture of the chloride of iron may be prescribed with reference to this condition. In obstinate cases flying blisters are useful. Valleix considers these as most likely to prove effective. The application of dry cups will sometimes afford relief.

Hyperæmia of Lungs. Hypostatic Congestion. Hypostatic Pneumonitis.

Active congestion or hyperæmia of the lungs, irrespective of inflammation, is rarely, if ever, a primary morbid condition, and is hardly to be considered as an individual affection. It may be produced by increased power of the heart's action, arising either from transient causes, such as the ingestion of alcoholic stimulants and mental emotions, or from hypertrophy of the right ventricle. It may be caused by the inhalation of stimulating or irritating vapors. Whenever the circulation in a considerable portion of the lungs is interrupted, more or less abnormal determination of blood must take place in the portions to which the flow of blood is unobstructed, as in cases of emphysema, lobar pneumonia, pleuritis, etc.

Passive hyperæmia or congestion is of more frequent occurrence, but is never primary or idiopathic. It is an effect of mitral cardiac lesions causing obstruction or regurgitation, or both combined. It is also consequent on feebleness of the action of the heart, especially of the right ventricle, as in cases of dilatation or fatty degeneration. In cases of general dropsy it occasions a disproportionate amount of hydrothorax. It gives rise to brown or pigment induration of the lungs (see p. 185).

Passive hyperæmia occurring in the dependent portions of the lungs is called hypostatic congestion. The conditions which favor the production of hypostatic congestion are enfeebled heart's action and the maintenance of the body in one position for a long time. It is met with in acute infectious diseases, in the aged, and in the course of chronic diseases which occasion general debility. The higher grades of hypostatic congestion result in a transudation of bloody serum. The condition of lung thus produced has been called

splenization. The affected lung tissue is of a dark red color, crepitates less than in health, and, upon section, a large quantity of blood and serum oozes out. In prolonged or in severe hypostatic congestion the so-called hypostatic pneumonia is frequently developed. It has been disputed whether this is to be regarded as an inflammatory affection or not. It seems to involve a low degree of inflammation. The lung tissue is dark red, friable, non-crepitant, and sinks in water. The whole lower lobe may be implicated, or only portions of it. Microscopical examination shows the pulmonary capillaries widely distended with blood, and the air-cells filled with blood-corpuscles, desquamated epithelial cells, and sometimes fibrin. The inflammatory condition is more analogous to certain forms of lobular pneumonitis than to lobar pneumonitis.

Congestion of the lungs, whether active or passive, compromises the respiratory function, *first*, by diminishing the capacity of the air-cells, and, *second*, by lessening the quantity of decarbonized and oxygenized blood returned from the lungs to the systemic circulation. The respirations are increased in frequency, and a sense of the want of air, or dyspnœa, is felt, *cæteris paribus*, in proportion to the degree and extent of the congestion. As regards physical signs, congestion, if marked or considerable, undoubtedly causes a certain amount of dulness on percussion; but this is not determinable if both lungs be alike congested, or in cases in which congestion of one lung follows certain affections in the other side of the chest, as in pleurisy with effusion, pneumo-hydrothorax, etc. Congestion also undoubtedly diminishes the intensity of the respiratory murmur; but if the murmur be changed in character, that is, if it be bronchial or broncho-vesicular, there is solidification from some cause. It is not probable that simple congestion gives rise to adventitious sounds or râles; nor does it occasion any vocal signs.

The treatment of active hyperæmia must have reference, of course, to the causative conditions and the circumstances under which it occurs. The disturbance of respiration, not only when the hyperæmia is bilateral, but when unilateral, as when one lung is consolidated or compressed, may be so great as to call for venesection. In most cases, however, dry cups applied to the chest, revulsives, and cardiac sedatives suffice for relief.

In hypostatic congestion, on the other hand, measures to increase the power of the heart's action are indicated, namely, digitalis, alcoholics, and alimentation. As a preventive measure in cases of prolonged disease, especially if the patient be feeble, constant recumbency on the back is to be avoided; the position of the body should be changed at intervals. Deep inspirations from time to time should be enjoined. In this way hypostatic pneumonitis may be prevented. The occurrence of the latter, in different diseases, not infrequently contributes to a fatal termination. In all diseases accompanied by much prostration, or of long duration, or when the subjects are feeble, important objects of treatment are the prevention and removal of hypostasis in the dependent portions of the lungs. These objects are often of prominent importance in cardiac diseases.

Œdema of the lungs will be considered under a separate heading (*vide* Chapter VIII.).

CHAPTER VI.

PULMONARY PHTHISIS.

Anatomical Characters—Clinical History—Pathological Character—Causation.

THERE are two schools of doctrine as to the nature of the disease usually called pulmonary phthisis. The one maintains the unity of the disease, that is, it is always tuberculous; the other contends for a duality, in other words, that in some cases the disease is tuberculous, and that in other cases, the larger number, it is essentially a chronic catarrhal or interstitial pneumonia. The leading advocates of the former view, after Laennec, are Rindfleisch, Cohnheim, W. Fox, and the modern school of French pathologists. Virchow and Niemeyer may be mentioned as exponents of the latter doctrine. Within late years the opinion has prevailed that in most cases of pulmonary phthisis, chronic inflammatory changes are of chief importance, tubercles being inconstant and secondary; but recently there has been a reaction in favor of Laennec's doctrine. It is now generally admitted by pathologists that in pulmonary phthisis, tuberculosis and chronic inflammation are intimately combined, that it is very difficult to separate the one from the other, and that the admitted inflammatory changes have, in part at least, a special character denominated variously, scrofulous, tuberculous, caseous, etc. The present edition of this work will still adhere to the position maintained in previous editions concerning the essentially tuberculous nature of pulmonary phthisis, and the names pulmonary tuberculosis and pulmonary phthisis will be used synonymously.

Anatomical Characters.—It will be impossible within the compass of this work to give more than a general outline of the principal morbid changes in chronic pulmonary tuberculosis. The morbid appearances are so manifold that no two cases of phthisis are exactly alike, so that it is impossible to give a generally applicable description of the gross appearances. It is more convenient, therefore, to describe separately the various pathological processes which are combined in different proportions in cases of the disease.

The dominating element in the pathological anatomy of pulmonary phthisis is *tubercle*. For an account of the histological structure and the nature of this product the reader is referred to Part First of this work (p. 47). Tuberculous nodules or granula are to be found, either with the naked eye or with the microscope, in the majority of cases of phthisis. When young, these nodules are gray and translucent, but they oftener appear yellowish, having undergone partial or complete caseous metamorphosis. Sometimes they are transformed into fibrous tissue, when they have a dense consistence, and are grayish or slate-colored. The ultimate submiliary granula coalesce to make large and small nodules, varying in size from a millet-seed to a pea, and perhaps larger. A favorite and early situation for the formation of miliary tubercles is in the walls of the small bronchi, especially, according to Rindfleisch, in the lobular bronchi, where they open into the alveolar passages. An arrangement, sometimes observed, of tuberculous nodules in the course of the finer bronchial ramifications, has been often compared to that of grapes

in a cluster. Tubercles may be formed also in any part of the connective tissue of the lung, in the walls of the bloodvessels and lymphatics, in the interlobular tissue, alveolar walls, and the pleura. In the majority of cases they are formed primarily at the apex of the lung in the bronchial walls.

In addition to the miliary tubercles and the cheesy masses resulting from their coalescence, there are patches which begin with a tuberculous infiltration of the lobular bronchi, and extend peripherally by a filling up of the air-cells and an infiltration of the alveolar walls with cells like those in tuberculous granula. These cells undergo the same caseous metamorphosis as those in miliary tubercles. The patches, in a certain stage of development, resemble closely large tuberculous nodules. They present a cheesy centre, in which, perhaps, the elastic fibres circumscribing the small bronchi and the air-cells may remain as the only evidence of structure. The peripheral zone contains embryonic cells, often combined with endothelioid cells and giant cells, as in the tuberculous granulum. A caseous or tuberculous pneumonitis and a caseous peribronchitis enter into the formation of these patches, to which the names infiltrated tubercle and pneumonic tubercle have been applied. Recent French writers, in widening the domain of tubercle, have revived the name infiltrated tubercle, and designate by it much which other writers refer to chronic inflammatory changes. Virchow regarded the nodular form, in distinction from diffuse infiltration, as an essential criterion of tubercle.

Whether or not we assume tubercle to be of inflammatory origin, it is certainly most intimately connected with inflammatory processes. Of these, the one known as *caseous*, or *tuberculous pneumonitis*, is the most important. This appears usually in lobular, rarely in lobar form. The alveoli become filled with cells resembling epithelial cells, with which lymphoid cells, fibrin, and red blood-corpuscles may be mingled in various proportions. The alveolar walls are usually infiltrated with cells. The solidified portions of lung are, in the fresh state, gray or reddish-gray in color, and, if moist, present the appearance of the gelatinous infiltration of Laennec. After a time, cheesy degeneration ensues, and the resulting yellowish-white solidified patches were called infiltrated tubercle by Laennec. There are different opinions as to the nature of this form of pneumonia which accompanies tuberculosis. Some consider it merely a catarrhal or lobular pneumonia, like that of children. Buhl calls it desquamative pneumonia, Rindfleisch scrofulous inflammation, and recent French writers, following Laennec, call it infiltrated tubercle. The cheesy masses resulting from this pneumonia, seem to have the same etiological significance as those from genuine tubercle, to have the same infective properties, to present, in many cases, the same gross appearances, to be most intimately connected with the presence of tuberculous granula, and yet to apply to them the name tubercle is to lose sight of all morphological criteria of this morbid product, except that of caseation. The designation tuberculous pneumonitis is the preferable one. The most recent investigations lead to the conclusion that the sharp distinction which Virchow drew between the caseous pneumonic and the tuberculous products cannot be maintained; and this is true, whether we admit with Cohnheim that a specific tuberculous virus inheres in the caseous material from both sources, or whether we regard the purely anatomical appearances. In certain cases of phthisis, particularly in some of those running a rapid course (phthisis florida), the pneumonitis may predominate over the tuberculous nodules, but it rarely happens that the latter are entirely absent.

Not only the air-cells, but all the structures which enter into the formation of the lung, may participate in the inflammation which accompanies pulmonary tuberculosis. Here we can do little more than enumerate some of these processes. The mucous membrane of the bronchi, particularly of those at the

apex, is early affected with inflammation. Ulcers, usually of tuberculous origin, are frequent. Cheesy plugs often occlude the bronchial tubes. Inflammation of the fibrous coat of the bronchi is called *peribronchitis*. The various forms of peribronchitis called tuberculous, caseous, fibrous, purulent, are sufficiently explained by these terms. Some form of peribronchitis is one of the constant attendants of phthisis. That which has been said concerning the intimate relation existing between tubercle and caseous pneumonitis, is equally applicable to peribronchitis.

To similar inflammatory changes in the outer coat of the arteries the name *periarteritis* is applied. The term *endarteritis* is given to an inflammatory thickening of the inner coat of an artery, by which process the lumen of the vessel is gradually encroached upon and may be finally obliterated. This *endarteritis obliterans*, as it is called, is frequently present in chronic phthisis, as in chronic inflammations in various parts of the body.

Inflammation of the interstitial tissue of the lung, leading to the formation of new connective tissue, is called *chronic interstitial pneumonitis*, and, in some degree, is present in all cases of chronic pulmonary phthisis. The new tissue encroaches upon the pulmonary parenchyma, usually leading to the obliteration of some of the air-cells and shrinkage of the affected portion of the lung. In so-called fibrous phthisis, there is an excessive formation of connective tissue and retraction of the lung. This form presents sufficient clinical peculiarities to demand special consideration which will be given in the next article.

Pulmonary phthisis is always accompanied with *pleuritis*, usually of the dry form, that is, without the effusion of liquid. It results in the formation of vascular adhesions which are, as a rule, most extensive and firmest at the apices.

Of non-inflammatory changes deserving mention in phthisis, are pigmentation with coal-particles and with melanine, particularly in newly-formed connective tissue, calcification of caseous material, atelectasis, compensatory emphysema, localized and general œdema.

After a period, varying much in different instances, *cavities* are formed in the majority of cases of phthisis. These are of two kinds, either those due to dilatations of the bronchi, bronchiectasies, or those resulting from excavation of the lung substance. The bronchiectatic cavities are common, especially in connection with much increase of the connective tissue; they do not attain a large size without leading to ulceration of the bronchial wall and the formation of excavations. The ulcerative cavities, vomicæ, result from a softening of the tuberculous and inflammatory cheesy material and its removal through the bronchi. The cavities enlarge laterally by a continuance of the same process in the adjacent lung tissue. Cases differ much as regards the number and the size of the cavities. The greater part of the upper lobe of a lung may be converted into a single cavity. The cavities are generally irregular in form, with ridges of pulmonary tissue in their walls, and are often traversed by bands of fibrous tissue containing bloodvessels, the rupture of which may be the source of dangerous hemorrhage. In cases of fatal hæmoptysis, the source of the hemorrhage is usually aneurisms of the arteries in the walls of the cavities. These aneurisms are usually about the size of a pea, and project from the side of the artery into the cavity. In recently-formed cavities the walls are thin and often sloughy; in old cavities the walls are dense and firm like the pyogenic membrane lining an old sinus. Cavities sometimes open into the pleural cavity and give rise to pneumo-pyothorax. This accident is usually prevented by pleuritic thickening and the formation of adhesions between the pleural layers.

As regards the amount of morbid products, pulmonary tuberculosis varies

much at the outset, in different cases. Cases also differ much as regards their progressive accumulation. In some instances an increase goes on steadily, that is, without intermission; in other cases, after a certain amount, there is no further increase for an indefinite period. Not infrequently products occur, as it were, in successive crops, at epochs more or less remote.

The tuberculous formations, as has already been mentioned, are situated first in the apex of one lung in the vast majority of cases, and in the progress of the affection they extend downward, more or less, towards the base; sooner or later they occur at or near the apex of the other lung, thence extending downward. Different collections of cases analyzed in order to determine whether the right or the left lung is most liable to be first affected, have furnished discrepant results, showing that there is no fixed law with respect to this point. Exceptionally the affection commences at the base and extends upwards.

A simple and convenient division into stages is based on the marked difference, as regards anatomical characters, before and after the formation of cavities. The first stage embraces the period during which the tuberculous products accumulate and soften, up to the evacuation in a liquefied state. The second stage extends from the time when cavities are formed to the termination of the affection. A stage of softening, distinct, on the one hand, from the period during which the caseous products, formerly called crude tubercle, are solid or semi-solid, and, on the other hand, from the cavernous stage, is superfluous, for the existence of such a stage cannot be predicated with any degree of certainty on either symptoms or signs. As regards the two stages, namely, before and after excavation, it is to be borne in mind that frequently, if not generally, both are represented at the same time in different portions of the lungs. After cavities have been formed in certain portions, more recent collections in other portions are still either firm or undergoing the process of softening.

In this division into two stages, it is assumed that the affection goes on to the formation of cavities. This is the rule; yet, exceptions to the rule are not very infrequent. If the tuberculous products be scanty and disposed in small disseminated nodules or tubercles, they may be absorbed. In some cases the animal constituents of the deposit may be infiltrated with lime-salts and become hard calcareous bodies which may remain imbedded in the lung, or, ulcerating into the bronchial tubes, they are expectorated. In these modes a cure of the local affection takes place in a certain proportion of cases. But a cure may also take place after the affection has gone on to the second stage. It is well ascertained that cavities, even of considerable size, may gradually contract, and, at length, perfectly cicatrize. In some cases in which cicatrization does not take place, cavities become lined with a non-secreting membrane, and they may remain nearly innocuous for an indefinite period.

Some writers have recognized, as a stage of the disease, a period anterior to the tuberculous deposit, which has been called the pre-tuberculous stage. It has been supposed that such a stage may be determinable by symptoms and signs. That both a general and local morbid condition precede the deposit can hardly be doubted, but that anatomical changes take place, which are represented by symptomatic phenomena, and which may be appreciated by physical exploration, is not established by clinical observation.

Clinical History.—In sketching the clinical history of this affection, the symptoms attending the development and the first stage will, in the first place, claim attention.

The affection is often remarkably insidious in its development. In a certain proportion of cases the pulmonary symptoms are preceded, for several weeks or months, by deteriorated general health, as denoted by loss of weight, impaired muscular strength, and a pallid aspect. These premonitions, however, are not constant, and, if they exist, are rarely sufficiently marked to excite the attention of the patient or others. In a pretty large proportion of cases, the pulmonary symptoms which may be considered as denoting the tuberculous affection are neither preceded nor accompanied by ailments of any description which lead the patient to suspect the existence of any disease. In the majority of cases, when the patient first comes under the cognizance of the physician, the previous history renders it probable that the affection has existed for several weeks, or, perhaps, months.

Of the pulmonary symptoms, the first which occurs is cough. Unless the affection be developed coincidently with an attack of bronchitis, which is not common, the cough is, at first and for some time, slight, dry, hacking, and perhaps excites little or no attention. Occasionally, however, it is, from the outset, a prominent symptom. The expectoration, for some time wanting, is at first small, and consists of frothy, glairy mucus. It progressively increases, becoming gradually more abundant, and at length solid and opaque. These symptoms proceed from irritation and circumscribed bronchitis. Hæmoptysis frequently takes place shortly after the occurrence of cough and expectoration. In some cases it precedes these symptoms. It is often the event which first excites any apprehension of serious disease, and leads the patient to seek medical advice. If cough and expectoration have existed for some time prior to this event, the patient had not heeded them, thinking they were due to a slight cold, and that they would shortly disappear.

Pain in the chest does not belong to the disease *per se*. Pain, however, is apt to occur, at times, more or less frequently, during the first stage of the disease, and is due to circumscribed pleuritis. The pain is sharp, lancinating or stitch-like, referred to the summit of the chest, and frequently shooting beneath the scapula. It varies at different times and in different cases in severity, being rarely sufficient to keep the patient in bed or even within doors, and it may continue for one, two, or three days. In the progress of the disease, the pain in these attacks is referred successively to both sides of the chest, and it may be most severe and frequent on the side in which the amount of disease is least. The attacks are considered by patients to be rheumatic or neuralgic. They possess considerable diagnostic significance, but they are of very little importance as indicating the amount or the progress of the disease. Intercostal neuralgia occasionally occurs, and is to be distinguished by the diagnostic points which have been presented in treating of that affection.[1] The respirations are usually increased in frequency, and the increase, other things being equal, is in proportion to the amount of the phthisical disease. This symptom may not attract the notice of the patient. It is apparent especially on exercise. It is rarely the case that suffering from dyspnœa is experienced, and, to ascertain the existence of this symptom, it may be necessary for the physician to observe for himself, and not trust to the statement of the patient. Even when, owing to the amount of disease, lividity is marked, dyspnœa is not always complained of.

Among other than pulmonary symptoms, the condition of the circulation, as represented by the pulse, holds an important place. During the first stage, more or less acceleration of the pulse is the rule, and this acceleration, although not great, is an important diagnostic symptom. The acceleration differs much in different cases. In general, it is in proportion to the activity of the disease.

[1] *Vide* page 191.

If the pulse be frequent, the disease is likely to be rapidly progressive. A certain proportion of cases are characterized by frequency of the pulse, which is also quick, vibratory, and compressible, qualities denoting morbid activity, but diminished power, of the heart's action. In these cases the career of the disease is apt to be short.

The temperature is more or less raised in proportion as the disease is progressive. The thermometer thus aids in the diagnosis of the disease, and, if the diagnosis be not doubtful, it affords evidence of the disease being progressive or otherwise. When it is a question as to the diagnosis, increase of temperature is evidence for, and absence of any increase is evidence against, the existence of the disease. In well-marked cases the increase is a measure of the activity of the disease, whereas a normal temperature denotes that the disease is non-progressive.

Daily exacerbations of fever may occur in the first stage. Toward evening the acceleration of the pulse is increased, with increased heat of skin, and sometimes a marked sensation of burning in the soles and palms; the cheeks may present a bright circumscribed flush, and after some hours the exacerbation goes off with perspiration. The exacerbation is sometimes preceded by a chill. Chills also occur without being followed by notable febrile movement. They may be pronounced and accompanied by rigor, or they are slight and transient, consisting, in some cases, of occasional shiverings or a sensation as if water were trickling down the back. Well-marked chills, followed by increased heat and perspiration, may occur with such regularity that the patient is supposed to have intermittent fever, and, under these circumstances, if the pulmonary symptoms be slight, the affection of the lungs may be for some time overlooked. I suppose there are few physicians of much experience in situations where they are liable to meet with intermittent fever, who cannot recall cases in which this error of diagnosis has been made. Fever of limited duration may be due to an intercurrent circumscribed pneumonitis.

As regards appetite and digestion, there is much diversity in different cases. In general, the desire for food is diminished, and the ability to digest food impaired. In some cases there is almost entire loss of appetite and even a repugnance to food. This is an unfavorable feature of the disease. Disorder of digestion is sometimes so prominent as to appear to be the chief malady. The physician should be on his guard against considering the cough in such cases as merely dyspeptic or sympathetic. Antipathy to fat is by no means constant; some patients take fatty articles of food freely without repugnance and with relish. And, on the other hand, not a few patients who are not phthisical have an antipathy to fat.

Diarrhœa occurs, in the first stage, in a certain proportion of cases. It may exist with and without a tuberculous affection of the intestinal canal, usually seated in the small intestine. Persisting or frequently recurring diarrhœa, accompanied by cough, be the latter never so slight, should excite suspicion of pulmonary phthisis, and the existence of this affection being ascertained, a tuberculous affection of the intestinal canal, as a secondary affection, is probable. Diarrhœa proceeding from tuberculous enteritis is an unfavorable symptom, diminishing the prospect of improvement. The seat of the affection is usually the Peyerian and solitary glands. It leads to ulcerations differing from those which are characteristic of typhoid fever in a tendency to extend in a transverse direction and to occupy only portions of the elliptical patches; also, in having hardened and raised margins. Tuberculous ulcerations are sometimes found in the large, as well as in the small, intestine, and they may be confined to the former. The ulcerations may lead to circumscribed peritonitis, and the peritoneal inflammation sometimes becomes general. Perforation of the intestine occasionally takes place, giving

rise to general peritonitis, provided the peritoneal surfaces over the ulcerated space within which the perforation occurs have not become adherent from previous circumscribed inflammation. Intestinal hemorrhage sometimes takes place, and I have known it to prove the immediate cause of death.

Impaired nutrition, denoted by diminished weight, is frequently one of the earliest symptoms. As a rule, reduction in weight continues as long as the disease is progressive; on the other hand, the disease may be considered as non-progressive if the patient be not losing weight, and, still more, if he be gaining in flesh. Defect in the chylopoietic processes is shown by anæmia which, in most cases, is an early symptom, and is frequently marked.

The muscular strength progressively diminishes if the disease be progressive, but here there is much variation in different cases. Patients are rarely compelled to keep the bed in the first stage, and they are generally able to be out of doors. Deficiency of breath, in some cases, precludes an amount of active exercise or labor for which muscular strength is sufficiently retained.

Suppression of the menses is a symptom significant of the progress of the disease; the menstrual discharge diminishes in quantity, and, in the course of the disease, ceases. Patients are apt to attribute importance to the suppression as a cause of their other ailments. It is, however, an event incidental to the disease, and does not claim special treatment. Facts do not show that suppression of the menses from other causes exerts an influence in the development of phthisis.

This disease does not tend directly to impair the intellectual faculties. The intellect frequently remains bright and active notwithstanding the progress of the disease. The feelings are usually cheerful and buoyant. Patients are hopeful respecting their condition; they depreciate their symptoms, and are reluctant to admit that they have a serious malady. This state of mind sometimes amounts to an infatuation which renders it difficult to obtain from the patient a fair account of the symptoms, and it is necessary for the physician to rely chiefly on the statements of others and his own observations. To such an extent is the absence of anxiety characteristic of the disease, that an opposite frame of mind militates somewhat against the existence of phthisis. Patients are readily persuaded that they are improving, and hence they fall an easy prey to quacks. They sometimes dislike to be told the truth, and take offence at an intimation that they are consumptive.

Proceeding to notice the points in the clinical history which distinguish the second stage, it is to be borne in mind that it is not easy, nor is it practically important, to draw an exact line of demarcation between the two stages. Successive phthisical irruptions are apt to take place, or the disease may be extending steadily, so that, while the local affection has advanced to the second stage in one part, usually near the apex, the first stage may be represented in other parts. The disease is to be considered as having advanced to the second stage when it has led to the formation of a cavity or of cavities of sufficient size to give rise to certain distinctive signs and symptoms. The symptoms of the first stage continue into the second, in most cases, being increased and modified by the existence of cavities.

The cough in the second stage usually becomes more prominent. It may be less irritable, and more exclusively for expectoration. It is troublesome and difficult in proportion as the contents of the cavities are not easily evacuated, owing to their size, want of free communication with the bronchial tubes, etc. The expectoration consists of liquefied phthisical products, matter furnished by the lining membrane of the cavities, and secretion from the bronchial mucous membrane. The quantity of expectoration is very variable, amounting in some cases, to only a few ounces, and, in other cases, to a pint or more daily.

The appearances of the expectoration are various. It is oftenest mucopurulent with more or less predominance of the characters of pus. In proportion as it is purulent, the sputa do not remain distinct, but run together to form a homogeneous mass. Sometimes a collection of the liquid expectorated presents a thick, opaque appearance not unlike that of pea-soup or gruel. The sputa are sometimes solid, remaining distinct, and, in falling upon the bottom of a vessel, assume a flat, round appearance like that of a coin, and hence are called *nummular sputa*. The sputa occasionally present yellow *striæ* which consist apparently of pus. The edges of the sputa are sometimes ragged; another appearance is that of small particles, resembling boiled rice, contained in the matter expectorated. It is very rare for a semi-softened, cheesy, morbid product to be expectorated; but, in a case under my observation, several masses of this description were raised, evidently due to an unusually large ulcerated orifice being established between a phthisical collection and a bronchial tube of considerable size. In this case, the signs of a cavity were developed directly after the expectoration of a large amount of matter which contained the partially softened masses. A sudden expectoration of matter, in considerable quantity, presenting a purulent or puruloid appearance, denotes the opening by ulceration of a so-called tuberculous abscess. Not infrequently this occurs repeatedly during the progress of the disease; but in many cases the ulcerated opening is at first small, and the liquefied matter escapes gradually into the bronchial tubes. The constituents, as shown by the microscope, are pus-corpuscles, epithelium, fatty granules, blood-disks, occasionally the yellow elastic fibre, and sometimes low vegetable organisms.

The quantity of matter expectorated is, in general, in proportion to the number and size of the cavities. It is usually more abundant in the morning than at any other period, owing to its having accumulated during sleep. Toward the close of life the act of expectoration becomes difficult on account of muscular feebleness, and the consequent accumulation in the air-passages not infrequently hastens death. Occasionally the matter expectorated and the breath of the patient emit considerable fetor due to decomposition of matters within the cavities.

Hæmoptysis occurs less frequently in the second than in the first stage; and, occurring in the second stage, it may be due to the rupture of the bands of pulmonary tissue which so often traverse tuberculous cavities, these bands sometimes containing vessels of sufficient size to furnish an abundant hemorrhage, or, more frequently, to rupture of the minute aneurisms in the walls of the cavities, to which reference has been made in the account of the anatomical characters. Sometimes the loss of blood in this way is sufficient to destroy life, but instances are rare. The hemorrhage, however, may contribute to a fatal result. I have known a large cavity to become filled with coagulated blood.

Hoarseness, or huskiness, and sometimes extinction of the voice, denote laryngitis, which may be developed in the first, as well as in the second, stage. Its occurrence is presumptive proof of pulmonary phthisis, the latter existing prior to the laryngitis.

Lancinating pains incident to circumscribed pleuritis recur in the second as well as the first stage, from time to time. Occasionally, both in the first and second stage, the pleuritis becomes general, and occasions more or less liquid effusion. So far as my observations go, they confirm the statement of Louis, that double pleuritis with effusion denotes the pre-existence of tubercle. Acute pain, suddenly developed, with embarrassed breathing, acceleration of pulse and prostration, point to perforation of the lung, and the signs of pleurisy with pneumothorax are to be sought for.

The pulse, as a rule, is more accelerated in the second than in the first

stage. Febrile exacerbations are oftener present and more marked, with burning of the soles and palms. The night perspirations are often copious, causing debility and great discomfort.

The appetite and digestion are more or less impaired, cases differing greatly as regards the symptoms connected with the ingestion of food. Diarrhœa is more frequently present, and is a more prominent symptom in the second stage, being connected often with intestinal ulcerations. If profuse and persisting, it has been distinguished as *colliquative diarrhœa*. Colliquative diarrhœa occurs at an advanced period of the disease although tuberculosis of the intestines does not exist. It is then due to defect of intestinal digestion, and to transudation from impoverishment of the blood. With the progress of the disease the body progressively diminishes in weight, and the patient is often reduced to an extreme degree of emaciation. The strength varies greatly in this stage. The patient may be confined to the bed for a greater or less period before death, but not infrequently strength is preserved sufficiently to be up much of the time, and even to go out of doors, within a few days or even a few hours of death.

Bulbous enlargement of the ends of the fingers, with incurvation of the nails, forming what are called *clubbed fingers*, is occasionally observed. This peculiar appearance is characteristic of phthisis, but it is not a pathognomonic symptom. It may be strikingly marked in connection with organic disease of the heart without phthisis. It occurs in cases of fibroid phthisis as often as in the form of the disease under present consideration. The toes present a similar appearance, but in a less marked degree. This symptom occurs only in cases in which the disease has existed for a considerable period. Of 1776 cases analyzed by Pollock, the fingers were more or less clubbed in 654, being a fraction under 27 per cent.

The mental condition in the second stage is frequently not less characteristic than in the first. The expectation of improvement, prolonged life, or even recovery, amounts, in some cases, to an insane delusion. Patients are sometimes occupied in forming plans for the future, when it is obvious to any observer that they are on the verge of the grave. They may insist to the last that there is no danger. Over and over again, in the hospital wards, I have been asked by patients reduced almost to skeletons, and too feeble to sit up for a moment, if there be any danger, or if they will recover. But whenever patients affected with this disease are satisfied that there is little or no hope of recovery, they generally become quickly and completely resigned.

Œdema of the feet and ankles is a symptom of the second stage, denoting notable failure of the circulation. For a time this may occur only after sitting or standing, disappearing after the recumbent posture has been maintained for some hours; but, at length, it is permanent, and may increase and extend over the whole of the lower extremities, rendering them unwieldy. When the œdema becomes thus marked, extensive and permanent, thrombosis of the crural veins is to be suspected, an event which is liable to occur in this disease. Coagulation in the crural vein on one side will account for the œdema in some cases in which it is either limited to, or is much greater in, one of the lower limbs. If the œdema be diffused over the body, constituting anasarca, co-existing disease of the kidneys is to be inferred; but the latter is a rare complication of pulmonary phthisis.

The clinical history is affected, in no small degree, by complications and co-existing affections. The occurrence of tuberculous disease of the intestines, tuberculous laryngitis, pleuritis with pneumothorax, and disease of the kidneys, has been already referred to. Chronic peritonitis is an occasional complication. The researches of Louis demonstrated that chronic peritonitis, not traumatic,

is almost invariably dependent on tuberculosis in this situation, and hence that, from the existence of the peritoneal affection, pulmonary phthisis may be inferred. Acute peritonitis, from perforation, is sometimes incident to the tuberculous affection within the intestinal canal. Meningitis, usually tuberculous, occurs as a rare concomitant in the adult, but not infrequently in early life. This co-existing affection accounts for the development of delirium and coma in certain cases. Perineal abscess, leading to fistula, is another complication occurring in a certain proportion of cases, proceeding probably from tubercle in this situation. Clinical observation shows that, as a rule, when this complication occurs, the amount of tubercle in the lungs is small or moderate, and the progress of the pulmonary affection is slow. An accumulation of fat within the liver cells is a morbid condition observed in a considerable proportion of cases, occurring oftener in women than in men.

The duration of this disease is extremely variable. In the vast majority of cases it is essentially a chronic affection, but sometimes it runs a rapid course, passing through its changes and destroying life in a few weeks. The disease in such cases has been known as "galloping consumption," or phthisis florida. It is different from that known as *acute miliary tuberculosis*, which will be noticed under a distinct heading. Distributing fatal cases into groups according to the duration of the disease, exclusive of the rapid cases just referred to, one group will consist of cases in which the disease continues from three to six months; in another group death takes place between six months and a year; in a third group the career extends from one to two years; and in another group the fatal termination is held in abeyance for many years.

Limiting attention to the cases in which, sooner or later, the disease proves fatal, its march is extremely irregular. It is not uncommon for little or no progress to be apparent for several successive weeks, months, or even years, and then the disease to advance with more or less rapidity. Distinct irruptions occurring at successive periods are frequently points of departure for the onward march of the disease; but cases differ much as regards the local destruction, and the rapidity with which softening, ulceration, and the formation of cavities take place. Further remarks on the march of the disease will be offered under the head of prognosis.

Pathological Character.—The pathological character of tuberculosis has already been considered in the first part of this work. In a practical point of view, the fact to be borne in mind is that pulmonary phthisis is not, primarily and essentially, an affection of the lungs. The local affection proceeds from a prior morbid condition of the system; in other words, it is a constitutional affection called the tuberculous cachexia or dyscrasia. Grounds for the foregoing statement as regards the constitutional origin of pulmonary phthisis will appear in proceeding to consider the causation.

Causation.—The causes may be divided into those which act, first, locally, upon the lungs, and, second, generally, or upon the system in producing the constitutional condition or cachexia. With respect to local causes, they are not sufficient in themselves to produce the disease. They act only as exciting causes. The disease is sometimes either preceded by, or occurs in connection with, some other pulmonary affection, namely, bronchitis, pleuritis, or pneumonitis. If this association be more than a coincidence, the latter affections only serve to determine the local manifestation, the cachexia already existing; that is, they act the part of the match when everything is ready for the explosion. These affections occur so frequently without being either accompanied or followed by phthisis, that it is certain they have no intrinsic tendency thereto; and, on

the other hand, in the great majority of cases, pulmonary phthisis is developed irrespective of these affections.

The statements in the foregoing paragraph are not in accordance with views held by some late writers, namely, Niemeyer and others. According to these views, the development of pulmonary phthisis is often dependent on bronchitis. Hence, the name proposed by Niemeyer, *chronic catarrhal pneumonia.* Niemeyer attributed the development of the disease, in certain cases, chiefly, or entirely, to a bronchitis or bronchial catarrh, attributing little or no importance to a diathetic or a constitutional agency. A question of this kind is settled, not by a theory based on histological observations, but by clinical facts. Now, the early clinical history, in cases of phthisis, shows, as already stated, that it is rarely preceded by bronchitis or bronchial catarrh. I make this positive assertion with the utmost confidence in its correctness, inasmuch as it is based on the study of a large number of cases with reference to the earliest symptoms and signs. Moreover, it accords with the clinical researches of Louis, which, as far as they go, are not less reliable and valuable to-day than when they were made, half a century ago. Aside from clinical facts, it is irrational to suppose that a bronchitis, which is a bilateral disease, should give rise to an affection almost uniformly limited, at first, to the apex of one lung. The doctrine that the development of pulmonary phthisis is dependent on bronchitis, or other local causes, rather than on an unknown constitutional agency called a cachexia, is the more to be protested against, since upon this doctrine are based prophylactic and therapeutical measures which are opposed by clinical experience.

Niemeyer attributed the production of phthisis, in some cases, to bronchorrhagia, the presence of blood remaining in the bronchial tubes being supposed to prove a local cause. As already stated, clinical observation, so far from affording ground for this opinion, goes to show that hæmoptysis is oftener a salutary event than otherwise, if phthisis already exist; and there is reason to conjecture that it may be sometimes a substitute for, and, therefore, preventive of, phthisis. But in some rare, exceptional cases, an attack of hæmoptysis appears to be the point of departure for either the development or the active progress of the disease.

To the conformation of the thorax was formerly attributed considerable causative agency. This doubtless arose in part from observing that phthisical patients often present contraction of the chest, occurring as an effect of the disease. Persons with great deformity of the chest are not specially prone to phthisis. So, also, the idea that the exercise of the voice may be a predisposing or exciting cause, has become obsolete; and observation shows that if any influence be derived from this source, it is conservative rather than causative.

The opinion appears to be entertained by some writers, that chronic pharyngitis, which is an exceedingly common affection in this part of the world, has a tendency to eventuate in pulmonary phthisis. This opinion is erroneous. After a large opportunity of observing cases of chronic pharyngitis, I have come to the conclusion that it generally denotes a condition of the system unfavorable to phthisical disease. The sebum-like matter which is liable to accumulate in the glands of the tonsils, and to be ejected by coughing in the form of round, hard pellets, are sometimes mistaken for tubercles. These may be distinguished from obsolete tubercles or pulmonary calculi by their being unctuous to the touch, and emitting, when crushed, a fetid odor.

The efficient causes must be sought for among those which affect the system. Were the essential nature of the disease understood, we might hope to reach, synthetically, the knowledge of its causation. A rational pathology and etiology must of necessity go hand in hand; but our present knowledge of

both is confined within narrow limits. The actual knowledge which we possess is derived from clinical observation and statistics, and there is room for further information to be derived from these sources. I shall state certain conclusions which are well grounded, referring the reader, for a fuller exposition of the facts on which they are based, to works treating at greater length of this most important branch of the subject.

Facts show the tuberculous diathesis in a certain proportion of cases to be congenital and inherited. Why a peculiarity of constitution rendering a person specially liable, at a certain age, to the development of this disease should be transmitted from parent to child, cannot be explained more than the fact that peculiar traits of physiognomy or mental character are inherited. The conclusion rests on observation. It is a matter of common remark that the offspring of consumptive parents are apt to become tuberculous. But it is to be borne in mind that, owing to the frequency of the disease, a tolerably large proportion of phthisical patients must have a consumptive parentage from mere coincidence; and it may be true that, sufficient consideration not having been accorded to this fact, hereditary influence has been overrated. Walshe's statistical researches appear to give support to this supposition. Interrogating a considerable number of hospital patients affected with the disease, namely, 162, he found that, of this number, in 26 per cent. either the father or mother, or both parents, were tuberculous.[1] He argues that this proportion is not much above that which would be expected from the prevalence of the disease irrespective of any hereditary influence. These statistics, however, are open to the criticism that the statements of hospital patients are not very reliable, and that, in a certain proportion of cases, the parents might subsequently become phthisical. Moreover, the number of patients interrogated, although considerable, was not large. The plan of investigation might be pursued further with perhaps a different result; and it would be more satisfactory to analyze cases in private practice with respect to this point.

A congenital and hereditary influence is most strikingly shown by facts relating to certain families. In another work I have cited the following instance, occurring under my own observation:[2] All the children of a family, seven in number, were victims of this disease in five years—the ages being between 18 and 23. The mother died of the disease shortly before the death of the first of the seven children who died. The father was a man of robust health. Another instance within my knowledge is as follows: A tuberculous patient was under my care in January, 1862, and subsequently died. This patient had lost eight brothers or sisters from the disease, and both parents. Two sisters, then living, were all that remained of the family. Another striking illustration is afforded by the following facts: Of a family comprising eight children, one died in childhood with convulsions, three daughters and one son have died with phthisis, another daughter and a son are now tuberculous, and the only remaining child, the eldest daughter, presents the history and signs of arrested tuberculosis. Both parents died tuberculous. The following statement, communicated to me by Dr. Henry E. Paine, of Dixon, Illinois, illustrates a congenital tendency without the evidence of inheritance: Mr. S. is 57 years of age, and in good health. His wife is 52, and well. No progenitors have been known to die with phthisis. All the children, five in number, died with this disease between 1853 and 1861—their ages respectively being, at the time of death, 23, 25, 24, 22, and 23. The following facts are interesting as showing a remarkable limitation

[1] British and Foreign Med.-Chir. Rev., Jan. 1849.

[2] Physical Exploration of the Chest, and the Diagnosis of the Diseases affecting the Respiratory Organs. 1866.

of the disease to one branch of a family: Two brothers married sisters. In neither family was there evidence of hereditary predisposition to phthisical disease. One of the brothers and his wife died of the disease. Of two sons and two daughters, both the latter and one of the sons have died with the disease; and the remaining son is probably phthisical. The other brother and his wife are living in good health, and, of several children, none have been affected with phthisis.

Facts, such as have just been cited, show that the tuberculous diathesis is sometimes inherent in the constitution and inherited. To what extent a congenital influence is involved in cases in which circumstances do not render it evident, must be left for conjecture. It is not irrational to suspect its existence in a large proportion of the cases in which proof is impossible.

The predisposition has relation to age. The disease is most liable to be developed between 20 and 30. The other decennial periods of life are arranged in the following series, according to the rate of predisposition; 30 and 40, 10 and 20, 40 and 50, 50 and 60, 0 and 10, 60 and 70, 70 and 80, 80 and 90, 90 and 100. No age is exempt from a liability to the disease, and it may affect the fœtus *in utero*.

Climate appears to exert an influence either for or against the development of the disease. The prevalence of the disease is less in climates either uniformly warm and dry, or uniformly cold and dry, than in those which are moist and subject to frequent alternations of cold and warmth. A high altitude affords protection against the disease. Jaccoud states that observations for fifteen consecutive years warrant him in asserting that in Alpine situations elevated 4000 feet, tuberculosis is almost unknown; and especially is this true of villages at an elevation of 5500 feet, where, in the language of the country, there are "nine months of winter and three months of cold weather." According to Dr. Hjaltelin, who resides in Iceland, the inhabitants of that country enjoy exemption from phthisis. The disease prevails to a much greater extent in cities than in the country, showing, doubtless, the operation of auxiliary causes in the former. It prevails more on the seaboard than in inland situations. The elaborate researches of Bowditch go to show that, in the State of Massachusetts, cases occur more frequently in localities in which the atmosphere is rendered humid by streams or marshes. Dr. Buchanan's observations show that, in England, cases are comparatively rare in dry, elevated situations. There is no foundation for the opinion that the terrestrial emanations known as malarial afford any protection against the disease. Newly-settled places are frequently exempt, for some time, from its prevalence to much extent; but the explanation of this fact is that the pioneers who compose the early population in these places are persons, generally, of sturdy, vigorous health, and the habits of life, in such a population, are protective against this disease. As regards season, the disease is oftener developed during the spring months and the hot months of summer than at other portions of the year.

The disease prevails much more among those whose pursuits are sedentary than among those whose occupation involves out-door life. Want of exercise, defective ventilation, deficiency of light, and the depressing emotions undoubtedly contribute to the production of the tuberculous cachexia. With reference to the influence of ventilation, the following researches of Dr. Guy, of London, are interesting: Taking hæmoptysis as a criterion of either tuberculosis or the tuberculous cachexia, Dr. G. interrogated 104 compositors who worked in apartments having less than 500 cubic feet for each person. Of this number thus situated, 12.50 per cent. had had hæmoptysis. He then interrogated 115 compositors who worked in apartments having from 500 to 600 cubic feet, and of this number 4.35 had had hæmoptysis. Of 101 compositors working

in apartments with more than 600 feet, only 1.98 had had hæmoptysis. The influence of the several causes just mentioned is seen in the greater liability of domesticated animals to tuberculous disease than of the same animals in a wild state. "The stabled cow, the penned sheep, the tame rabbit, the monkey, the caged lion, tiger, or elephant, are almost invariably cut off by tuberculous affections."[1]

The infrequency with which the disease is found in the post-mortem examinations of those who have died from intemperance, has led to the supposition that the use of alcohol antagonizes the tuberculous cachexia. Assuming that there is ground for this supposition, it would be irrational to reject it because it may be made to sanction the unnecessary use of alcohol; but the moral, as well as physical, considerations which this application involves are, of course, to have due weight in affecting the conduct of practitioners. The following statistical facts relating to the prophylactic influence of alcoholism have been communicated by Leudet: Of 121 persons addicted to the use of alcohol, twenty were tuberculous, and these twenty were the only intemperate persons among 600 tuberculous patients.[2] There is reason to believe that habits of diet unduly restricted as regards variety and quantity, either from choice or necessity, may contribute to the development of the disease.

Pregnancy has been supposed to antagonize the tuberculous cachexia, and marriage has sometimes been advised as a prophylactic and even curative measure. Facts, however, do not afford support to this supposition. In the collection of cases which I have analyzed, 87 were married, and under 40 years of age. Of these 87 cases, the disease was developed during pregnancy in 10, and in 12 within a few weeks or months after confinement.[3] The inference is, that pregnancy either directly or indirectly has a decided and considerable influence in the etiology of the disease. The researches of Grisolle and Dubreuilh show that the development of the disease not infrequently takes place during pregnancy, and when tuberculous patients become pregnant, the progress of the disease is hastened rather than retarded. Of 155 cases in patients who had recently been confined, analyzed by Pollock, in 48 the disease was developed during pregnancy, and in 51 it began at confinement.[4] An analysis by the same author, of 94 cases in which the disease was developed after confinement, showed that it began during lactation in 54. Clinical facts are opposed to the notion that the progress of the disease is retarded by lactation.

Certain diseases exert an influence, on the one hand, to promote, and, on the other hand, to prevent, the development of tuberculosis. It rarely occurs in persons affected with pulmonary emphysema. Persons affected with cardiac lesions which interfere with hæmatosis, rarely become tuberculous. On the other hand, measles and typhoid fever leave the system in a condition favorable for the development of the tuberculous cachexia. Are they who suffer in early life from a scrofulous affection of the lymphatic glands of the neck especially prone to pulmonary tuberculosis in after-life? I have been led to think that this question may be answered in the negative. I have collected a number of cases in which young and middle-aged persons presenting the characteristic cicatrices on the neck were free from tuberculous disease of the lungs; and, on the other hand, it is extremely rare to find these cicatrices in persons who are affected with pulmonary tuberculosis. Assuming the tuberculous and the scrofulous cachexia to be the same, it would seem that it is, as it were, exhausted by the deposit in the glands of the neck, and that after-

[4] The Elements of Prognosis in Consumption, by James Edward Pollock, M.D., London, 1865.

ward it is not likely to recur. Contrary to what might be expected *à priori*, anæmic persons rarely become tuberculous. Pollock states that of 125 carefully noted cases of anæmia, with murmurs, in none was there any sign of tubercle. The association of anæmia with pulmonary tuberculosis, except as a complication or an effect, is certainly rare. It is rare for phthisis to follow an attack of lobar pneumonitis.

In conclusion, of the various agencies which are involved, more or less, in the causation of pulmonary phthisis, it is difficult to assign to each its proper relative importance. It is probable that this is pre-eminently a diathetic disease; but it is impossible to determine whether the diathesis be always innate, or whether, in a certain proportion of cases, it be acquired. Do the causes which contribute to the development of the disease produce the diathesis, or do they act solely by producing the cachexia, the diathesis already existing? Our present knowledge does not enable us to answer this question. Yet our limited knowledge of the causation is of immense value in its practical application to prophylaxis and treatment.

The production of miliary tubercles in certain inferior animals by inoculating them with matter obtained from the tuberculous products in man has been already referred to (*vide* Part I. p. 49). The discovery of this interesting and important fact naturally leads to the inquiry whether phthisis may not sometimes be caused in man by the inhalation of a virus contained in the breath or exhalations from the body of tuberculous patients. The doctrine of the contagiousness of the disease has now, as hitherto, its advocates, but the general belief is in its non-communicability. The advocates for the doctrine have relied for its support especially on the number of instances in which husbands and wives have been affected in succession. If the communicability of the disease by inoculation establish the existence of a specific virus, this fact lends much support to the possibility of contagiousness.

CHAPTER VII.

PULMONARY PHTHISIS—(Continued.)

Diagnosis—Prognosis—Treatment.

DIAGNOSIS.—An early diagnosis, in cases of pulmonary phthisis, must rest mainly on physical signs, in connection with the history and symptoms. The physical conditions, when the local affection is considerable or when the disease is advanced to the second stage, are represented by well-marked signs rendering the diagnosis easy and positive. The diminished volume of lung at the apex, which frequently occurs, causes a depression at the summit of the chest on the side most affected, and, owing to pleuritic adhesions, the expansion, at the summit, is less than on the opposite side. The scapula, on the side most affected, is often restrained in its movement upward in inspiration, contrasting, in this respect, with the opposite scapula. These signs, obtained by inspection, are available in a certain proportion of cases. Percussion elicits relative dulness, and sometimes even flatness. Exceptionally, over the solidified portion of lung, the resonance is tympanitic.

A tympanitic resonance over a circumscribed space, and the varieties of this resonance called cracked metal and amphoric, point to the existence and situation of cavities. The respiratory sound, obtained by auscultation, is either bronchial, or broncho-vesicular, or cavernous, and, not infrequently, these different signs are found in different situations in the same case. The first represents considerable or complete solidification, the second moderate or slight solidification, and the third a cavity or cavities. The cavernous respiration, in some cases, has an amphoric quality. The correlative vocal signs are likely to be present, namely, either bronchophony with the loud and whispered voice, or exaggerated vocal resonance, and, in rare cases, pectoriloquy. More or less of these auscultatory signs are available in the great majority of cases. And these, taken in connection with the cough and expectoration, the emaciation and other symptoms belonging to the history of the disease, render the diagnosis an easy problem.

It is only in cases in which the local affection is moderate or small, the symptoms being, at the same time, less marked, that the diagnosis is difficult; and the difficulty, in such cases, is rarely great, provided the physician have a good practical knowledge of physical exploration. Inspection may, in these cases, furnish the same signs, but less marked than in cases of a considerable local affection. As a rule, slight or moderate, but distinct, dulness on percussion may be ascertained. The exception to this rule is when more or less of the pulmonary lobules become emphysematous, and then the resonance is altered, although not diminished—it is vesiculo-tympanitic. A comparison of the respiratory murmur on the two sides at the summit, will be likely to show abnormal changes, namely, the characters of the broncho-vesicular respiration. So, also, on a comparison as regards vocal signs, the vocal resonance and the bronchial whisper may be found to be increased. The same is true of vocal fremitus. A careful exploration with reference to the foregoing signs will furnish direct evidence of the disease.[1]

In addition to these signs, there are several, occasionally present, which are inferentially evidence of phthisis. These may be distinguished from those already enumerated, as the accessory signs of the disease. Fine bubbling or the subcrepitant râles, heard within a circumscribed space at the summit of the chest on one side, are highly significant of tubercle. They proceed from secondary circumscribed bronchitis. A crepitant râle, in like manner limited to a small space at the summit on one side, has the same significance, being due to secondary circumscribed pneumonitis. Crumpling and crackling sounds are significant, provided they are limited to the summit on one side. A pleural friction sound limited to the summit on one side, denotes a secondary circumscribed pleuritis. Other accessory signs are an abnormal transmission of the heart-sounds and an interrupted or jerking respiration. The diagnostic significance of all these signs, it will be observed, depends on their situation at the summit of the chest on one side. Separately they are not sufficient for the diagnosis, but, co-existing with the direct signs, namely, dulness on percussion, broncho-vesicular respiration, exaggerated vocal resonance, and increased bronchial whisper, they serve to confirm these signs and render the diagnostic evidence positive.

The diagnostic points pertaining to symptoms, to which attention is to be directed in determining whether the disease be, or be not, present, when the signs are not so well marked as to render the diagnosis easy, are as follows: (*a*) Cough and expectoration, not succeeding an attack of acute bronchitis, and not connected with chronic pharyngitis; the cough at first dry, and,

[1] For a fuller account of the physical diagnosis, *vide* Clinical Medicine by the author, 1879; also, Manual of Auscultation and Percussion, 2d edition, 1879.

afterward, an expectoration, at first small and transparent, and becoming gradually more abundant and opaque. (*b*) Stitch-pains at the summit, not connected with intercostal neuralgia. (*c*) Chills not referable to malaria. (*d*) Hæmoptysis. This is always a symptom of great significance, but the fact is to be borne in mind that it occurs, in a certain proportion of cases, without being associated with tubercle. (*e*) Accelerated breathing. (*f*) Loss of weight. (*g*) Pallor or anæmia, not otherwise explicable. (*h*) Hoarseness or huskiness of voice, proceeding from chronic laryngitis. (*i*) Chronic peritonitis, not traumatic. (*j*) Suppression of the menses. (*k*) Buoyancy of mind, instead of despondency.

Facts which render the existence of a hereditary predisposition probable are to be taken into account in the diagnosis. The age of the patient is another point. As the discrimination frequently lies between phthisis and chronic bronchitis, it is to be considered that, except in aged persons and those affected with disease of the heart, chronic bronchitis is comparatively so rare that the chances are in favor of the existence of phthisis. The chances are still greater, if, in addition, are excluded the cases in which chronic bronchitis is associated with asthma and emphysema, affections which rarely co-exist with phthisis.

In certain cases the solidification represented by physical signs at the time of an examination of the chest, depends, to a greater or less extent, on an intercurrent, transient, circumscribed pneumonitis. This can only be ascertained by repeated examinations of the chest after certain intervals of time. The solidification, so far as due to superadded simple or ordinary pneumonic inflammation, will be found to disappear, leaving that which is caused exclusively by the phthisical affection. It is important to bear in mind the liability to a temporary increase of solidification of lung, in cases of phthisis, from an intercurrent pneumonitis which may not reveal itself by any distinctive symptoms.

Prognosis.—The prognosis is extremely unfavorable, in view of the fact, that, in many, if not most, parts of the world, the mortality from this disease exceeds that from any other, exclusive of fevers and affections which prevail epidemically or endemically. Yet the mortality from the disease has undoubtedly diminished within the past three decades. This must be obvious to medical observers whose professional experience extends backward for forty or fifty years. The fact is also shown by the statistics published by the registrar-general of Great Britain, and by the mortuary reports of the large cities in this country. The explanation of the fact is probably to be found in improved views as regards the management of the disease. The diminution which has already taken place in the death-rate from this disease, affords ground for the hope that its formidable character may be still further mitigated.

The different modes in which the disease may pursue a favorable course have been already stated. The entire deposit may be absorbed, or calcification of the caseous products may occur, forming the so-called obsolete tubercles or calculi, and these may remain quiescent, or they may find their way into the bronchial tubes and be expectorated. Cavities may completely cicatrize. In these modes complete recovery may take place. This, of course, is the most satisfactory termination And next to this is the persistence of cavities without any fresh products, the cavities giving but little inconvenience for an indefinite period, and even through a long life. According to these different modes in which the course of the disease is favorable, cases may be divided into those in which an arrest takes place without recovery, and those in which the arrest is followed by recovery. Whether re-

covery follows, or not, depends on the extent of the local affection and other circumstances. Not infrequently an arrest takes place, with or without recovery, and, after the lapse of months or years, a fresh irruption occurs. The latter, then, is not properly a continuance of the disease, but a recurrence of it. These distinctions are pathologically just and practically important.

The facts relating to the proportion of instances in which the disease ceased to progress, either with or without complete recovery, as developed by the analytical study of the collection of cases recorded by me during a period of thirty-four years, are as follows: Of 670 cases, the list embracing a few cases of acute tuberculosis and interstitial pneumonia, 44 ended in recovery. In my work on Phthisis, published in 1875, the details of the history of each of these cases are given sufficiently to render evident the correctness of the diagnosis and the fact of recovery. In 31 cases the disease was either arrested or ceased to progress, complete recovery from the lesions incident thereto not taking place. Thus, in 75 cases either recovery took place or the disease became non-progressive. The ratio of recoveries (1 to 15) is not fairly shown by these facts, inasmuch as the termination in a considerable number of cases was not ascertained. This statement of course applies equally to the ratio of cases in which the disease is either arrested or its progress ceases without recovery. A fair conclusion is, that in not an extremely small proportion of cases complete recovery may be hoped for, and that this conclusion is equally true in respect of the disease becoming non-progressive without complete recovery. A recurrence of the disease, after periods varying from one and a half to over six years, was noted in six cases. In five of these cases, the recurrent disease terminated fatally. In the single cases in which the recurrent disease did not prove fatal, a second recurrence took place more than twenty years ago, the patient now living and free from any pulmonary affection.

I may claim, in behalf of my clinical studies in relation to Phthisis, that thereby is established the fact that, in a certain proportion of cases, this disease is self-limited; in other words, it ends in recovery from an intrinsic tendency thereto. Of the 44 cases ending in recovery, in 23 there was no medicinal treatment to which an arrest of the disease could be attributed. In several there was no medicinal treatment whatever, and, in the remainder, the treatment consisted of simple tonics, cough palliatives or remedies to meet some other symptomatic indication. In none could the treatment be considered as curative. Of the 31 cases in which the disease became non-progressive without complete recovery, in 15 there was no medication by which, as might be supposed, the disease was controlled, and in several none whatever. In respect of hygienic treatment, in some cases of both groups there was no change whatever in habits of life; in other cases there were changes involving more favorable circumstances pertaining to hygiene; but in a considerable number those changes were not of such a character that a potential influence could be attributed thereto. It is probably correct to say that the changes may have favored recovery or non-progression, but were inadequate to cause an arrest of the disease. The histories in these ten groups substantiate self-limitation in cases of phthisis. The disease may cease to progress and end in recovery because it is self-limited.

Assuming that phthisis in a certain proportion of cases is a self-limited disease, the practical bearing on the conclusions to be drawn from medicinal and hygienic treatment is important. If the disease may end in recovery exclusively from an intrinsic tendency, it is evident that self-limitation must be more or less operative in the cases which recover under different measures of treatment. Self-limitation is a factor co-working in certain cases with curative measures, and, it may perhaps be added, sometimes effective in spite

of measures which tend to obstruct its operation. On the other hand, when this factor is feeble or wanting, curative treatment is not likely to prove of much avail. Evidently, in drawing conclusions respecting the curative effect of remedies, allowance is to be made for this factor. The extent of its co-working doubtless differs much in different cases, in some, being sufficient in itself, and in others, either considerable, moderate, or slight. Considering that its agency has not been hitherto recognized, it is easy to explain the well known fact that, from time to time, various methods of treating phthisis, apparently successful in some striking instances, have failed speedily to meet the expectations excited by their apparent success. Whatever was really due more or less to self-limitation, was attributed solely to the methods of treatment, and when the former was feeble or wanting, the latter gave little or no evidence of curative power. This is the rationale of the *post hoc ergo propter hoc* fallacy which has always had much to do with false deductions from therapeutical experience.[1]

Is it possible, by means of symptoms and signs, to judge whether there be, or be not, an intrinsic tendency to a favorable course and termination? Can a given case be investigated with reference to the existence and degree of this tendency, or is self-limitation always a matter of retrospection? The bearing of these questions on the prognosis is obvious. It is extremely desirable to be able, in individual cases, to form a judgment respecting these points of inquiry. It is practicable to obtain important information, warranting something more than a mere conjecture, from both symptoms and signs. What I shall state in this connection is based upon the clinical study of cases which exemplified recovery or cessation of progress from self-limitation, as contrasted with other cases.

The symptoms which warrant hope and sometimes even an expectation of a favorable course and termination, relate especially to the circulation, the body-heat, alimentation, and nutrition. Persistent frequency of the pulse, fever, anorexia, and progressive emaciation oppose reliance on self-limitation. *Per contra*, encouragement on this score is warrantable when the pulse is but little, if at all, more frequent than in health, the temperature of the body not much, if any, raised, the appetite in a great measure retained, and loss of weight inconsiderable. These and other symptomatic conditions which render it possible, if not probable, that the disease tends intrinsically to recovery, may be summed up in one word—tolerance. In proportion as phthisis is well tolerated, there is room for hoping that it will prove self-limited. If the tolerance be deficient, self-limitation is proportionably weak or wanting.

The signs obtained by auscultation and percussion represent the local physical conditions, the latter representing the degree and extent of the pulmonary affection. Other things being equal, the chances of recovery by self-limitation are greater, the smaller the amount of phthisical lesions and the space in which they are localized. I have been led to believe that phthisis not very infrequently ends by self-limitation before it has made sufficient progress to develop well-marked physical signs. In other words, there are abortive cases of this as of other diseases. How often are the traces of an old, small phthisical affection found in bodies dead with various diseases! I have met with instances of, as I supposed, abortive phthisis. These cases are apt to be misapprehended, the more because the general belief is that exceptions to the rule of progress are extremely rare.

I have learned, however, from histories which I have recorded and reported, that self-limitation may be exemplified notwithstanding a large area of solidi-

[1] *Vide* paper entitled "Self-limitation in Cases of Phthisis," by the author, in the "Archives of Medicine," New York, June, 1879.

fication followed by cavities of considerable size. The most reliable of the points on which a hopeful prognosis is to be predicated in these cases, is the confinement of the affection within circumscribed limits, that is, absence of signs denoting progressive extension or general diffusion. The extent and degree of lesions, if circumscribed, do not prevent the disease from being self-limited, but they stand in the way of complete recovery. In most of the cases of non-progressive phthisis without recovery, the lesions do not admit of restoration, although the phthisical disease may be said to have ceased—the lesions in these cases remain as sequels like, for example, the intestinal ulcerations resulting, in tropical climates, from acute dysentery.

Aside from the symptoms and signs to be taken into account in forming a judgment respecting self-limitation, my clinical studies have shown that age and sex have no special significance. They show, what could not have been anticipated, that heredity is not incompatible with an intrinsic tendency to recovery. Among my cases of recovery are two sisters, now living and well, who alone remain of a phthisical family, both parents, three sisters, and two brothers having died with phthisis. The two sisters now living, one of whom recovered more than 15 and the other more than 20 years ago, had no important treatment, either medicinal or hygienic, whereas there were changes of climate and the persistent use of remedies in the cases of a dead sister and two brothers. These facts render striking the fact of self-limitation in the cases which recovered. Confining myself to a simple statement, I will add that my histories afford evidence that profuse and repeatedly occurring hæmoptysis, chronic laryngitis, pleurisy with effusion, and perineal fistula, are by no means in all cases unfavorable as regards prognosis based on self-limitation.

The disease proves fatal generally by asthenia. It is rare for the destruction of lung to be so great as to destroy life by apnœa. The patient is gradually worn out by the protracted disturbance occasioned by the disease, conjoined with progressive emaciation and exhaustion. The development of pneumo-hydrothorax from perforation is apt to prove fatal in a short time, and sometimes by apnœa. Acute peritonitis from perforation has been known to occur, and this affection is likely to prove rapidly fatal. Meningitis is another complication which hastens the fatal termination.

Hæmoptysis is very rarely an immediate cause of death. A few instances have fallen under my observation. A profuse and rapid flow of blood may occasion death by suffocation, the blood filling the bronchial tubes. A case of this kind has fallen under my observation. In two cases among those which I have analyzed, death was attributable to profuse hemorrhage from a phthisical cavity. The analytical studies of Ware and Walshe proved that, as a rule, hæmoptysis is a favorable event as regards prognosis. My own clinical studies led to the conclusion "that cases in which hæmoptysis occurs show a larger number of recoveries, and a notably greater proportion of instances of arrest and of tolerance, than cases in which hæmoptysis does not occur."

Treatment.—The point of departure for the consideration of the management of phthisis is the pathological fact that the local affection is the expression of a general or constitutional morbid condition. The great object of treatment is the removal of this constitutional morbid condition or the cachexia. Measures addressed to the pulmonary affection are of secondary importance. The chief end to be kept in view is the prevention of further increase of this affection, or, in other words, an arrest of the disease. It is immensely desirable for the arrest to take place as quickly as possible, while the local affection is limited and the pulmonary damage proportionably small;

and, with a view to a speedy arrest, the importance of an early diagnosis can hardly be overrated.

Is the cachexia removable by any known special remedy or remedies? This question is to be answered in the negative. Various remedies have been supposed to exert a specific curative influence. Thus, going back only a quarter of a century, during this period wood-naphtha, cod-liver oil, phosphate of lime, the hypophosphites, the chlorate of potassa and the benzoate of soda have successively been advocated as effecting a cure in cases of pulmonary tuberculosis. Few, if any, at the present moment consider either of these remedies, or any other remedy, as specifically curative. This, however, is by no means saying that remedies are not useful in cases of pulmonary phthisis. Important indications are to be fulfilled by remedies, but it should be clearly understood that far more reliance is to be placed on hygienic, than on medicinal, measures of treatment.

Certain therapeutic measures heretofore employed, to a greater or less extent, under the guidance of false pathological views, do harm rather than good. In this category belong bloodletting, either general or local, blisters and other severe modes of counter-irritation, mercurialization, antimonial and other nauseating preparations, emetics and cathartics. These are contra-indicated. In general terms, everything is to be avoided which tends to impair the appetite, disorder digestion, and lower the vital powers.

The measures indicated are those which strengthen and invigorate. These terms, although lacking scientific precision, have a practical significance sufficiently intelligible. Directing attention to the measures which fall under the head of hygiene, these relate to diet, exercise in the open air, clothing, mental encouragement, and change of climate.

The diet should be generous as regards quantity, quality, and variety. The articles should be highly nutritious and adapted to the digestive powers. All the varieties of wholesome food which the patient is able to take with relish should be allowed, and the appetite should be encouraged as much as possible. With respect to the kinds of food to be particularly recommended, there are no general rules applicable to all patients. Meats, milk, farinaceous articles, and the different vegetables are to be combined in relative proportions according to the choice, habits, and experience in individual cases. It is desirable that cream, butter, and other fatty articles should enter into the diet as largely as possible without inducing disgust and disorder of digestion. The same remark applies to sugar. The intervals between taking food should be such as will secure the largest amount of nutriment which can be taken and digested during the twenty-four hours. In short, it is far from desirable to arrange any fixed system embracing details of dietetics to which all patients are expected to conform. The object is to nourish the body to the fullest possible extent, and this requires, in every case, the co-operation of the physician and patient. Deficiency of appetite, especially for nutritious articles of diet, and weak or disordered digestion, are serious difficulties in the way of successful management. Much may be done by persevering efforts on the part of the patient, and he should, therefore, be made to understand the object which it is desired to effect.

A diet consisting largely, or even chiefly, of fresh milk has undoubtedly proved sometimes successful, and a trial of it may be advised when the appetite is deficient, or when other articles of food occasion dyspeptic disorders. Goats' milk and asses' milk are rarely used in this country. They have heretofore been, and are still, to some extent, in European countries, considered as preferable to the milk of the cow. In order to carry out effectually the "milk cure," as it is sometimes called, milk should not only constitute the chief article of diet, but it should be taken largely.

Exercise in the open air, or, as I would prefer to say, out-of-door life, is, of all measures, the most important. In 1863[1] I analyzed the recorded histories of sixty-two cases in which an arrest took place, with a view to the points in the treatment which were common to all or a greater or less number. In twenty of these cases the arrest took place under hygienic measures without medicinal treatment. In these cases the most important point of agreement related to change of habits as regards exercise and out-of-door life. In respect to this point, there was also an agreement in the cases in which medicinal measures were employed. The following extract from the paper contains a summary of the facts, with the general conclusions: "The most striking and valuable of the results of the analytical study of these cases is their almost uniform agreement as regards change of habits with respect to exercise and out-of-door life at the time of the arrest. Excluding the seven cases in which the arrest was attributable solely to an intrinsic tendency, and two cases in which the facts with respect to this point were not noted, of the remaining fifty-three cases, in all, save three, the histories show a greater or less change of habits to have been made; and in many cases the change consisted in relinquishing sedentary callings for other pursuits, in order to carry out more effectually the desired reformation. I am well satisfied that here is the foundation for the successful management of pulmonary tuberculosis. I would rank exercise and out-of-door life far above any known remedies for the cure of the disease. There are grounds for believing that the advantage of a change of climate mainly consists in its being subsidiary to a change of habits as regards exercise and out-of-door life. So deeply impressed am I with the correctness of this view of the regimenal management of the disease, that I cannot express myself too emphatically in trying to enforce its practical importance." My subsequent clinical studies have corroborated the facts and views contained in the foregoing extract.

Phthisical patients should sleep in well-ventilated rooms. In conformity with popular notions they are apt to fear the cool or cold air of night. A fire may be kept in sleeping-rooms in the winter season, but the windows should be kept open. Dr. James Blake, of San Francisco, California, has reported several cases in which most favorable results followed living in the open air during the summer months, at an elevation of from three to five thousand feet above the sea, in the coast range of the mountains of California where the temperature is very equable, and no rain falls for five or six months. The patients did not even sleep in tents, but were in the open air during night and day.

Exercise in the open air should be accompanied by either mental recreation or occupations which interest the mind. It should, as far as possible, be incidental to pursuits which engage the attention. Adopted simply as a hygienic measure, it will rarely be persisted in. It is often essential, therefore, for patients to make a radical change in business, or, if they be able to devote their time to the restoration of health, hunting, sporting, travelling, etc., are to be resorted to as means of securing the union of out-of-door life with an agreeable exercise of the mental faculties. Over-exercise of the muscles is to be avoided. Patients sometimes, supposing that the benefit from muscular exercise is proportionate to its amount, carry it to the extent of producing a degree of fatigue and exhaustion which is injurious. It is not from the amount of physical exertion, but of out-of-door life with such exercise as is well borne, that benefit is to be expected.

The body should be protected against atmospherical changes, the temperature and functions of the skin being maintained by warm clothing. The

[1] Trans. N. Y. Acad. of Med., 1863.

garments worn next the surface should be made of a material which is a good non-conductor of heat, namely, either wool or silk. But a superfluity of clothing is to be avoided. The object is to provide adequate protection without an undue accumulation of heat and perspiration. In a cold or temperate latitude, during the winter season, a waistcoat of buckskin or chamois leather, worn, during the daytime, over a light woollen or silk shirt, is to be recommended to patients of either sex, as securing the proper protection without the inconvenience of being bundled with an overplus of garments. The feet should be well guarded against cold and wet. Properly clothed, the patient, if he be strong enough to go out of doors, should rarely be kept within doors by the state of the weather, but should resolutely keep up habits of out-of-door life, despite the ordinary changes of temperature and winds, remaining in the house only on inclement days.

I have frequently known the sponge bath to be taken daily by tuberculous patients, with apparent benefit. It may be safely tried and continued, provided it be followed by an agreeable glow. The temperature of the water used should be from 64° to 68° Fahr. It is to be borne in mind, with reference to this measure, as well as exercise in the open air, that the susceptibility to attacks of bronchitis is less, the more the exposure, and, also, that an attack of bronchitis does not usually exert any unfavorable influence on the tuberculous disease. Many patients are deterred from going out of doors, when the weather seems unfavorable, by needless apprehension of taking cold.

The proportion of cases in which an arrest of the disease is apparently either effected or promoted thereby, is sufficient to authorize the physician to encourage patients strongly to employ the hygienic measures which have been briefly considered. The influence of the disease on the mind is to induce either an expectation of recovery without effort, or resignation to death. It is important to make patients understand that very much depends on their own exertions. One of the great difficulties in the way of successful management is a passive, patient, tranquil frame of mind, which cannot be aroused to vigorous efforts. Persons endowed with resolution, energy, and perseverance, other things being equal, are more likely to struggle successfully with the disease than they who are deficient in these mental qualities. The measures which have been considered, if not successful in effecting an arrest of the disease, tend to retard its progress, and render the condition of patients most comfortable while life lasts.

Change of climate, as a means of effecting a cure of pulmonary tuberculosis, has been a fruitful topic for discussion. It does not fall within the scope of this work to enter into a full discussion of this topic. I shall present, briefly, certain considerations in connection with the question in individual cases, "Shall I try change of climate, and, if so, where shall I go?"

It may be assumed that a change of climate is frequently useful, and it appears sometimes to effect an arrest of the disease. The judgment of patients or their friends, in the matter, is not of much value, because it is usually based on the knowledge of a few cases, or perhaps of a single case, in which benefit may, or may not, have been apparently obtained. Change of climate, therefore, is to be advised under certain circumstances.

It may be taken for granted that there is no specific influence in any climate. It would be therefore needless to inquire if there be one particular place on the globe to be preferred above all others. Observation shows that different climates are suited to different cases. In general, the advantages which belong to climate pertain to altitude, uniformity, and dryness. As regards the latter, while a dry climate is generally preferable, some patients appear to do best in situations in which the atmosphere is warm and humid.

With respect to temperature, a uniform cold climate is best for some cases, and a uniform warm climate for other cases. Of late years, the custom has been gaining ground of sending patients to a cold latitude, and I have known of a number of instances in which the climates of Minnesota and Colorado have proved highly serviceable. On the other hand, I have known of many instances in which a change to a warm climate has appeared to accomplish all that could be desired. What circumstances, then, are to guide in deciding whether a cold or a warm climate will be likely to prove most advantageous? The feelings and choice of the patient are to have considerable weight. If, when in health, more vigor and enjoyment are habitually experienced in summer than in winter, a warm climate will probably be best, and, if the reverse be true, a cold climate is to be preferred. The condition of the patient as regards feebleness is an essential point. If so feeble as not to be able to live out of doors in cold weather, or if the reaction from the impression of cold be slow and imperfect, a warm climate is more suitable. It is rarely proper to send patients to a cold climate if the disease be considerably advanced, and, as a rule, a cold climate is better suited to men than women.

With reference to the particular place to be selected, it should contain resources for occupation and mental interest. There must be inducements for out-of-door life. I have known patients accustomed to active habits, to suffer intolerably from ennui in going to places where the supposed excellence of climate was the only inducement. It is often better to move about from one place to another than to remain stationary; as soon as a place becomes tiresome, it is best to leave it. Travelling in foreign countries, without any special regard for climate, is often the best plan, the advantage consisting in the interest and inducements to out-of-door exercise derived from a succession of new scenes. A sea-voyage in warm latitudes is generally useful, and if patients be fond of the sea, a long voyage, if practicable, may be advised. Many patients under my observation have resorted to sea-voyages; and I can affirm that, while in not a few instances the benefit has been marked, I have never known any harm to ensue. I have known several instances in which patients, in an advanced stage of the disease, the strength being much reduced, have taken long voyages with notable improvement. A change is often useful when there is no superiority on the score of climate, because it is in this way only, in certain cases, that relief from the cares and anxieties of business can be secured. As a rule, it is desirable to avoid places which are especially resorted to by phthisical patients, for the reason that seeing constantly examples of the different phases of the disease is likely to have an unfavorable moral effect. On this score sanitaria for phthisical patients are open to objection. Well-managed sanitaria, however, may have advantages relating to the systematic employment of regimenal measures, to diet, etc.

The habits and taste of the patients are to be considered. Persons who are dependent on the associations and comforts of home and friends for their happiness, will not be likely to be benefited by being sent away, especially if alone and among strangers. The stage of the disease and the rapidity of its progress are points of great importance. It is cruelty to send to a distance patients who are in a condition admitting of but little prospect of improvement, and who will probably not live to return. The amount of damage which the lungs have sustained, as determined by physical signs, as well as the symptoms, is to be taken into account, before deciding with regard to change of climate. And if a change be made and prove effectual, it becomes an important question whether, if practicable, the change shall not be permanent. An arrest of the disease does not extinguish the diathesis, and the safest course, undoubtedly, is to take up a residence in a climate in which the

cachexia is less liable to be reproduced, than in the climate in which it has been already developed. Finally, in forming an opinion of the importance of change of climate, it is to be considered that the progress of the disease will be unfavorable in a large proportion of cases, whatever may be the change or changes made; an arrest of the disease is not to be expected save in a small minority of cases. The fact that, of the persons who make trial of change of climate, the number who are not apparently benefited greatly exceeds the number who find this measure either successful or beneficial, should not discourage resorting to the measure so long as in a small proportion of cases it proves effective. Another consideration is to be added, namely, a change of climate not infrequently appears to retard the progress of the disease, rendering the patient more comfortable and prolonging life, although an arrest of the disease be not effected.

The foregoing remarks on change of climate were contained in the fourth edition of this work (1873), and they are retained in the present edition without any material alteration. In my series of clinical studies relating to phthisis (*op. cit.* 1876), I endeavored to deduce some conclusions from the cases in which change of climate entered into the histories. In 74 cases this was an important, and, in some instances, the chief measure of treatment. Of these 74 cases, in 9 the disease ended in recovery, and in 13 it became non-progressive. The proportion of 22 out of 74 cases is large enough to warrant the conclusion that a salutary influence was due to climate. Moreover, studying the histories closely, it appeared that, in 34 additional cases, there was evidence of improvement, leaving only 11 cases in which no benefit followed the change of climate. While self-limitation doubtless played an important part, it cannot account for these results to the exclusion of climatic influence.

These results relate to different climates collectively. A great number of places were resorted to by different patients: Minnesota, Colorado, California, New Mexico, the Southern States of the Union, Nice, Mentone, Egypt, South America, etc. My cases were insufficient to determine the comparative value of different climates. In undertaking to do this we have to deal with a complex problem. A fair comparison would require the histories of a considerable number of patients in each one of the various resorts embraced within the range of inquiry. There must at least be an approach to uniformity in all the cases as regards the stage of the disease, the extent of the local affection, and other circumstances. No single observer can accumulate data sufficient for such an undertaking. It would, however, be fair to take the results of all climates as a standard for reference, and bring into comparison the results of the analytical study of a considerable number of cases observed at any one, or a greater or less number, of the different places of resort. This might be done by observers residing in these different places. In this way very valuable data could be obtained for judging of the comparative advantages of different climates. The value of such data would be incomparably greater than any theoretical opinions in regard to the benefit of altitude, dryness of the atmosphere, temperature, the presence of ozone, pine woods' exhalations, etc. If, in addition to comparing results in particular places with those of different climates collectively, a comparison were to be made with the proportion of cases in which there is either recovery or cessation of progress without change of climate, it would be practicable to estimate, with some approximation to accuracy, curative climatic influences disconnected from the accessory circumstances, prominent among which is self-limitation. Single examples of recovery, however remarkable, are entitled to little weight as evidence of the curative effect either of climate or any particular measure of treatment. In one of the most striking of the

instances which have fallen under my observation, the recovery took place in this city, and without any important medication. The signs of excavation gradually disappeared in this case, the site and size of the cavity being indicated by a permanent circumscribed depression of the chest-wall. This was nearly twenty years ago, and the patient is now free from symptoms of pulmonary disease. The efficient factor in this instance must have been self-limitation. How often is it that individual instances like this one are considered as illustrative of the curative efficacy of a particular climate, or of some other measure of treatment!

In conclusion, while it must be a great relief to physicians to have formed convictions which prompt a ready and positive answer to the question so often asked—"What part of the world is best suited for phthisical cases?"—it will be long before such convictions can have as a basis adequate numerical facts. Meanwhile, they whose minds are not committed to a belief in the permanent value of any particular climate, must exercise judgment according to circumstances in individual cases, as regards, first, the propriety of a change; second, the climate to be selected; and, third, whether, or not, a change should be permanent.

As coming within the scope of hygienic treatment, marriage may be referred to. Physicians are sometimes consulted respecting the propriety of fulfilling a marriage engagement when one of the parties is affected by phthisis. My clinical studies (*op. cit.*) go to show that the effect of marriage on a phthisical patient, irrespective of pregnancy, is not unfavorable, a conclusion perhaps at variance with the opinion generally held. Regarded from a purely medical standpoint, the objections relate to the unfavorable influence of pregnancy, if the wife be affected, the risk of phthisical offspring, and the possible communication of the disease from either the husband to the wife, or *vice versâ*. The physician should state these objections. Whether, regarded from other points of view, they should prevent marriage, in particular cases, is not for him to decide. My experience is that, whatever advice be given, the sentiments determine the action in these cases.

Passing to consider remedies which enter into the management, I place under this head alcohol, without discussing the question whether it is properly so regarded, or whether, as was claimed by Todd, it is alimentary rather than medicinal. Clinical experience shows that in a certain proportion of cases alcohol has a salutary effect. In some cases this effect is marked; in other cases alcoholics in any form are not well tolerated, and, if their use be persisted in, they may prove hurtful. If the immediate effect be that of a cordial, that is, if they produce a sense of comfort; if they be followed by a feeling of increased strength and a greater disposition to exercise; if they do not excite the circulation or nervous system, benefit may be expected from their use. *Per contra*, if their immediate effect be discomfort; if they be followed by a feeling of increased weakness and less disposition to exercise, and if they excite the circulation or nervous system, they will not do good, and they may do harm.

As regards quantity, they may be given as freely as they can be taken without discomfort, without a sense of weakness or indisposition to exertion, and without excitation of the circulation or nervous system. The limitation in quantity is to be determined by the same circumstances which indicate their use, or, in other words, by their immediate effect. And, guided by these circumstances, it will be found that some patients will tolerate a large, some a moderate, and some only a small quantity. Phthisis is one of the diseases which, in certain cases, induce a remarkable tolerance of alcohol. Some patients who cannot take, without excitation, alcohol in any form in consid-

erable doses, are able to take it without this effect, and with benefit, in a very small quantity repeated after short intervals.

The form to be used is another practical point of inquiry. Whatever be the form used, I believe the remedial principle to be alcohol. But no one form is equally applicable to all cases. Some patients are benefited especially by spirits, some by wine, and some by malt liquors. Of the different varieties of spirits, wine, and malt liquors, each is best suited to some cases. The selection of the form to be used in individual cases must be decided by the preference of the patient and experimental trials. As a rule, food should be taken with alcoholics.

The extracts of malt now in vogue, cannot be regarded as substitutes for alcoholics, and it seems absurd to attribute to them anything beyond a certain amount of alimentary value.

There is an important matter connected with the employment of alcoholics which should not be ignored. I refer to a risk of forming habits of intemperance. If their remedial use involve this risk, it becomes a question how far we are warranted in incurring it. But in no case in which I have employed them has there been developed, so far as I know, a craving which rendered it difficult to relinquish their use. I am not aware that in a single case among the great number in which I have advised their use, has a patient fallen into intemperate habits. I certainly am not prepared to advocate the use of alcohol as a prophylactic; that is, to sanction indulgence among those who believe or fancy that they are in danger of becoming phthisical. In persons with the unfortunate idiosyncrasy which leads to an irresistible craving on the slightest indulgence, the immediate effects would always contra-indicate their use. And finally, when employed as a remedy, alcoholics are not to be taken as a means of conviviality, nor for any other than a curative influence. Observing these precautions, we may expect to secure their remedial agency without exposing our patients to a calamity which, in a moral point of view, would be greater than failure to arrest the disease.

With regard to cod-liver oil, not stopping to discuss the propriety of classing it among remedies, I proceed to state the practical points connected with its employment in cases of phthisis. All clinical observers unite in according to it more or less value. Its usefulness in a certain proportion of cases can hardly be doubted. Of the cases of arrested or non-progressive phthisis which I have analyzed, in several the treatment consisted exclusively in the use of cod-liver oil and hygienic measures. How much importance is to be attached to an intrinsic tendency, and how much to hygiene, in these cases, cannot be determined, but an examination of the circumstances belonging to the individual histories goes to show that a certain amount of salutary influence belongs to the oil.

The amount of curative influence which cod-liver oil, as of any remedial agent, exerts, cannot be accurately defined, because it is impossible to determine the proportionate amount of influence that may be exerted either by self-limitation of the disease or by hygienic measures, but, practically, this is of less importance than to ascertain whether a remedy be useful, be the degree of usefulness greater or less. If a remedy have considerable influence, it is, of course, more desirable to employ it than if the amount of influence were small; but let the influence be never so small, we are not, on that account, warranted in withholding it in a disease of such gravity as this. Practically, the question of the use or non-use of the oil relates to individual cases. Clinical observation shows that it is not useful in all cases. I shall give, briefly, the rules which my own experience has led me to adopt respecting its use and non-use.

If it be taken without great repugnance, if it do not impair the appetite or

digestion, nor occasion derangement of the bowels, it may be expected to do good. If it produce any of the effects just named, its propriety is questionable. It is best to begin with a small quantity and increase to the maximum quantity, which is from half an ounce to an ounce three times daily, taken near the time of meals, either before or after, as choice or experience may dictate. It is generally best tolerated after meals. Of the different oils, some patients tolerate best the pale and others the brown variety. I have repeatedly known patients to take by preference the crude oil obtained at fish markets. If the pure oil be not well tolerated, some one of the preparations containing lime or other ingredients, to divest it of its repulsiveness, may be substituted. Of course, in a given volume of the latter, patients get a quantity of oil diminished by the bulk of the added material. Observations made by Dr. A. H. Smith, and other members of a committee of the New York Therapeutical Society, show that the addition of fifteen minims of ether to each half ounce of oil enables patients to take this remedy, when, without the addition of the ether, it disagrees. The ether may sometimes be given with advantage half an hour after the oil has been taken.[1] Caoutchouc dissolved in the spirits of turpentine and prepared as a confection, has been largely used by Dr. T. R. Varick, instead of the cod-liver oil, with apparent benefit.[2] Glycerin has been thought to be useful as a carbonaceous medical food.

All remedies which improve appetite, digestion, assimilation, and nutrition are in a greater or less degree useful. Hence, quinia, salicin, strychnia or nux vomica, the bitter tinctures or infusions, and the mineral acids meet indications in cases of this disease. The chalybeate tonics are not without utility. That they favor the occurrence of hæmoptysis is an opinion not well grounded, and, had they this effect, it might be evidence for, rather than against, their utility. Arsenic and minute doses of mercury are to be included in this class of remedies.

Certain pulmonary symptoms claim attention. Expectorant remedies, as a rule, are not called for. They diminish appetite, occasion nausea, and disturb digestion. But remedies to allay superfluous cough, that is, cough not required for expectoration, are useful. For this end the succedanea of opium, namely, hyoscyamus, conium, belladonna, haschisch, chlorodyne, and hydrocyanic acid, may be prescribed, but, if these prove inefficient, opium in some form is required. The paregoric elixir will often suffice. Patients should be instructed not to yield to the disposition to cough, but to resist it whenever it is not effective. The habit of coughing unnecessarily is, in a great measure, under voluntary control. Soothing inhalations are sometimes useful in allaying the irritation which excites cough. The vapor of water, or spray, impregnated with conium or opium, may be inhaled. I have known the vapor of chloric ether to be highly useful as a palliative. All irritating inhalations are hurtful. The oxalate of cerium, in doses of from 5 to 10 grs. three times daily, has lately been employed with much success as a cough palliative. Its effect upon the stomach is that of a tonic.[3]

With reference to the injection of tuberculous cavities with a solution of the nitrate of silver or other medicated liquids through the larynx and trachea, it is sufficient to say that, aside from the difficulty of the operation, and the impossibility of limiting the application of the injected liquid to cavities, nothing beyond a palliative effect could be expected from this measure were it ever so successfully executed. The latter statement applies to the injection of cavities after making an opening into them through the chest-wall.

[2] *Vide* N. Y. Med. Record, Nov. 1, 1873.
[3] *Vide* article by Dr. Robert Cheesman in the N. Y. Med. Record, June 12, 1880.

The reported cases in which it has been resorted to, do not offer much encouragement to expect benefit from this procedure.[1]

Certain complications furnish indications for treatment. Attacks of dry, circumscribed pleurisy call for mild revulsive and soothing applications, such as sinapisms, liniments, or the belladonna plaster. Local bleeding by leeches or cups is never required. The pain incidental to these attacks generally passes off in a few days at furthest. The treatment of coexisting laryngitis will be considered in Chapter XII. Diarrhœa, dependent on tuberculous enteritis, is to be kept in check by astringents and opiates, the latter being used with as much reserve as is consistent with the object to be attained. Chronic peritonitis claims only palliative measures. Perineal fistulas should be allowed to continue without surgical interference.

In the progress of the disease, symptoms other than those relating to the chest require palliative measures. The night perspirations are frequently the source of great discomfort. The mineral acids, especially the dilute sulphuric acid and gallic or tannic acid, frequently afford relief. The external application of an astringent, such as alum dissolved in spirit, is sometimes effective. Belladonna or atropia is an effective remedy. Dyspnœa may be mitigated by ethereal preparations.

Paroxysms or exacerbations of fever are sometimes, in a measure, controlled by full doses of quinia. If the temperature be high, this remedy is indicated as an antipyretic. Sponging of the body may be resorted to in order to reduce a high temperature.

A comparison of the measures of management now generally pursued in this disease, with the measures in vogue half a century ago, shows a complete and radical change. Formerly, general and local bloodletting, catharties, emetics, mercurials, counter-irritation, low diet, and confinement within doors, were sanctioned by teachers and writers, and entered, more or less, into the treatment usually adopted. At the present time, the measures which are most approved are, in all points, the reverse. The latter are based on more correct pathological views, and the results of clinical observation. It is not unreasonable to hope that, at some future time, a remedy or remedies may be discovered capable of exerting a special influence over the disease, but, in the mean time, reliance is to be placed on an early diagnosis, the employment of remedies which, directly or indirectly, may exert, to a greater or less extent, a salutary influence, and, above all, on the hygienic measures which tend to invigorate and strengthen the system.

CHAPTER VIII.

FIBROID PHTHISIS. ACUTE MILIARY TUBERCULOSIS. GENERAL TUBERCULOSIS.

THERE is no sharp line of demarcation between fibroid phthisis and other forms of chronic pulmonary phthisis from a pathological point of view; but in its typical manifestations, regarded from a clinical standpoint, it presents sufficient peculiarities to warrant separate consideration. In such typical cases the lung is shrunken in size, with a corresponding retraction of the chest wall, and often a lateral deviation of the spine. The external appearances are like those which follow chronic pleurisy. The pleura is much thickened by the development of firm connective tissue, and the pleural surfaces are adherent. In the substance of the lung there are firm, dense bands and masses or nodules of fibroid tissue, frequently deeply pigmented. Cheesy and calcareous masses are often lodged in the black or grayish indurated tissue. There are, as a rule, numerous and extensive bronchiectases. Ulcerative cavities may also be present. One lung is usually in a more advanced stage of the disease than the other; so that the morbid appearances often seem to be confined to one side. Usually tuberculous granula are evident to the naked eye. The microscope shows the presence of tubercles, often of the most exquisite giant-celled type, in the lung. These undergo the fibroid metamorphosis to which reference has already been made. They are frequently situated in the bands of fibrous tissue. Tubercles with cheesy centres are also usually present. Some of the larger fibroid masses may present the tubercular tissue in a diffused form. In addition to the tubercles, there is chronic inflammation of the interstitial tissue of the lung. The alveolar septa, the interlobular, and the peribronchial connective tissue become increased in amount, the air-cells and bronchi are compressed, and many of them obliterated. The new connective tissue may be rich in lymphoid cells, or the cells may be few in number, and spindle-shaped. According to the amount of caseous or tuberculous pneumonitis present, there exist all stages of transition between typical fibroid phthisis and the ordinary form of pulmonary phthisis,

The names chronic interstitial pneumonitis and cirrhosis of the lung (Corrigan) have also been applied to this form of phthisis. It is doubtful whether a pure cirrhosis or chronic interstitial inflammation of the lung exists comparable to that of the liver. Certainly the majority of the cases of so-called fibroid phthisis are tuberculous, as has been described. But, at least, some of the cases of chronic pulmonary inflammation resulting from the inhalation of fine foreign particles, such as bits of steel, of coal, etc. (knife-grinder's, coaler's phthisis, etc.), seem to be examples of pure chronic broncho-pneumonia and interstitial pneumonia.

This variety of phthisis is comparatively rare. In an exceedingly small proportion of cases it is preceded by acute pneumonitis; but in these cases it is perhaps most rational to regard the succession of the two diseases as due to coincidence. This may also be said of the cases in which it has been observed to follow bronchitis. In the majority of cases the age of patients is under forty years.

The local symptoms are cough, with more or less expectoration, and want

of breath on exercise. The matter expectorated is often notably fetid, and sometimes suggestive of gangrene. Circumscribed gangrene occasionally occurs; but the fetor generally is due to the decomposition of muco-pus, from its detention in the cavities incident to bronchiectasis. Hæmoptysis, either slight or profuse, occurs in a considerable proportion of cases.

The disease may exist for an indefinite period without notable emaciation or debility; but, sooner or latter, hectic paroxysms occur, diarrhœa is not uncommon, the appetite fails, and there is, of course, a corresponding defect of nutrition. The fingers may become clubbed. General dropsy occurs in a considerable proportion of cases. This is due to dilatation of the right side of the heart, an effect of the obstruction of the pulmonary circulation, that is, assuming the absence of valvular cardiac lesions.

As regards physical signs, aside from the contraction of the chest, there is more or less dulness on percussion, rarely flatness; and the resonance elicited is often tympanitic. The tympanitic quality is marked in proportion as bronchiectasis is a concomitant lesion, and, of course, it is most marked when the dilated bronchial tubes are free from morbid products. Saccular dilatations may occasion cracked-metal and amphoric resonance. Either ordinary cavernous or amphoric respiration may be heard in certain situations. In other situations the respiration may be bronchial or broncho-vesicular. In some situations the characters of cavernous and bronchial respiration may be combined. On the other hand, there may be absence of respiratory sound over more or less of the affected portions of the chest. The vocal signs are those denoting pulmonary solidification and cavities, namely, bronchophony, increased vocal resonance, and sometimes pectoriloquy. Bubbling and gurgling râles are often present. The dilatation of the right side of the heart may give rise to a tricuspid regurgitant murmur, and to a jugular pulse. The shrinkage of the lung may cause considerable displacement of the heart. If the left lung be the seat of the affection, the heart is raised and carried to the left; if the right lung be affected, the heart is sometimes removed to the right side of the sternum.

As regards diagnosis, the ordinary form of phthisis is excluded by the extent of the damage, taken in connection with the fact that the affection is especially marked on one side, by the absence of the emaciation which generally characterizes the former, and by the long duration often with little or no progress. This differential diagnosis is less easy when the affection is bilateral than when it is unilateral. Affections with which it may be confounded are chronic pleurisy and carcinoma. Chronic pleurisy, after the removal of the effused liquid, does not furnish the signs of solidification, and perhaps of cavities, which belong to the clinical history of this disease. Carcinoma of the lung is generally secondary to carcinomatous disease in some other situation; the cancerous cachexia is often marked; there is progressive and perhaps rapid wasting of the body, and the progress of the disease is more rapid.

Fibroid phthisis involves lesions which do not admit of recovery. Sooner or later the disease ends fatally. But in many instances life is destroyed by some complication or intercurrent affection. An acute pneumonitis affecting a lobe of the sound lung, or an attack of acute bronchitis, may prove fatal. The ability to resist any severe disease is, of course, impaired. Alone, the disease ends fatally by slowly progressive exhaustion; but existing alone, it may be tolerated for a great number of years.

The treatment has for its most important object, maintenance of nutrition and strength. The measures for this object are remedies to promote appetite and digestion, a nutritious and abundant alimentation, together with climatic

and hygienic influences which tend to invigoration. Palliative measures, having reference to cough and expectoration, are indicated. Expectorants are useful by preventing the detention of muco-pus in the bronchial tubes, the decomposition of which increases the bronchial inflammation. The inhalation of the vapor of turpentine is useful. Disinfectant inhalations are indicated if the expectorated matter or the breath be fetid.

Acute Miliary Tuberculosis. General Tuberculosis.

This is an acute general disease characterized anatomically by the presence of tubercles in most of the organs of the body. Although not properly a local disease of the lungs, it is most convenient to consider it in connection with chronic pulmonary and fibroid phthisis.

The tubercles are found in a fresher state than in cases of chronic phthisis. They have undergone less caseous metamorphosis, and are surrounded with less diffuse inflammation. The organs almost constantly affected are the lungs and pleura, the liver, spleen, medulla of the bones and omentum. The thyroid gland, the endocardium, choroid of the eye, kidneys, pia mater, and lymph glands are very frequently involved—in fact, tubercles have been found in nearly all of the vascular tissues.

Acute miliary tuberculosis only exceptionally supervenes upon chronic phthisis. The lungs often present old slate-colored indurations and cheesy nodules in the apices, but these may be found after death from various diseases. The lungs are studded with small, grayish, firm nodules, which by the microscope can be demonstrated to be an agglomeration of submiliary tubercles. The nodules are surrounded by a zone of hyperæmic lung tissue, in which the air-cells contain desquamated epithelium and inflammatory products to a variable amount. The tubercles, especially in the more prolonged cases, may have undergone cheesy degeneration, in which case they will appear as yellowish-white nodules. Some of the apparently tuberculous nodules may be found under the microscope to be foci of broncho-pneumonitis. Tubercles are usually present in the pleura, which is often the seat of ecchymosis and of fibrinous exudation. Acute inflammation of the bronchial mucous membrane co-exists. The other organs which may be involved, present the tubercles also as either gray or yellowish granula, according to the presence, or absence, of caseous degeneration. In general, the tubercles present the typical endothelioid and giant-celled structure. (*See* Part I. p. 48.) There are, however, exceptions. In the pia mater, the tubercles usually appear as fusiform enlargements on the smaller arteries. The microscope often reveals only an infiltration of the adventitia with lymphoid cells. Giant-cells are not usually met with in the pia tubercles. The tubercles are apt to be most numerous at the base of the brain in the fissure of Sylvius, about the optic chiasm, and in the neighborhood of the pons, but they are by no means confined to these regions. Meningitis is a frequent attendant of tuberculosis of the pia mater. The tubercles in the kidney may be typical in structure, or they may represent only accumulations of lymphoid cells between the tubules. Tubercles in the liver are generally minute, often microscopic in size. The tubercles of the omentum are often accompanied by proliferation of its endothelium. The peritoneum may be studded with tubercles, with or without coincident peritonitis. More or less enlargement of the spleen is usually present.

Various attempts have been made to explain the nature and the source of the infection in acute miliary tuberculosis. The subject of the inoculability of tubercle has been discussed in Part First of this work (p. 49). An hypothesis advanced by Buhl has been widely accepted. He considers that acute general tuberculosis is produced by auto-infection from some indifferent cheesy centre

in the body. He based his theory upon the frequency with which he found in this disease such caseous nodules, particularly cheesy lymphatic glands, somewhere in the body. But he himself admits that in not a few cases these primary caseous foci are not to be found. It has also been pointed out that the greater number of the primary cheesy masses, especially those in the lymphatic glands, are themselves of tuberculous origin. On the other hand, the mere presence of caseous material in the body cannot itself suffice to produce general tuberculous infection, as is evident from the infrequency with which general tuberculosis follows chronic pulmonary tuberculosis, notwithstanding the extensive caseous deposits in the lungs in the latter disease. Admitting the existence of a local caseous focus of tuberculous origin in the majority of cases of acute miliary tuberculosis, it is necessary to explain in what way the whole body becomes infected. Here, as in other general diseases, it seems most natural to assume the entrance of the infecting material into the blood-current. In this connection the observations of Ponfick and of Weigert are of interest. The former observed in several cases of acute general tuberculosis, especially in children, a tuberculous change in the wall of the thoracic duct, and the latter found tuberculous deposits in the walls of the pulmonary veins. From both of these sources the tuberculous poison could readily make its way into the circulation, there being good reasons for the assumption that these deposits antedated the general tuberculosis. The origin of the primary tuberculous deposits received no explanation. Sufficient data are not yet at our disposal to enable us to generalize from these few observations.

With reference to the symptomatology and diagnosis, it is to be noted that the name acute miliary tuberculosis is limited to cases in which tubercles involve, not a single organ, such as the lungs, the pia mater, or the genito-urinary tract, but a large number of organs. The lungs may be predominantly affected, but tubercles exist also in other parts.

Cases of this disease are rare; they occur mostly after puberty and before the middle period of life, but no age is exempt from a liability to the disease. The theory of the existence of a special tuberculous virus has been referred to in Part I. p. 49. The causes are unknown. The disease is certainly never attributable to extrinsic causes which act locally upon the lungs. It is not a sequel of bronchitis, pleurisy, and lobar pneumonia. It supervenes sometimes on chronic pulmonary phthisis; but there is very little ground for the absurd statement made by Niemeyer, that the "greatest danger for the majority of consumptives is that they are apt to become tuberculous." Secondary acute tuberculosis, however, accounts for the fatal termination in a few of the cases of phthisis. I have given examples in my work on Phthisis. All that can be said of the causation, in the present state of knowledge, is that it involves a diathetic condition.

The general symptoms denote a febrile disease. The temperature of the body is more or less raised, but there is much variation in this regard in different cases. There is sometimes hyperpyrexia. Variations in the pyrexia at different periods in the same case are sometimes marked. The pulse is usually rapid, ranging from 120 to 140 per minute. There is complete anorexia, and the prostration is great.

The respirations are usually notably frequent, from 30 to 60 per minute. Cough is more or less prominent. The expectoration varies, and is sometimes small, or even wanting. It proceeds from secondary bronchitis. It may contain blood in streaks. Hæmoptysis is an occasional event. Among the cases given in my work on Phthisis, is one in which the disease commenced with a profuse hæmoptysis. In some instances there is much suffering from dyspnœa, but patients do not always complain of a sense of the

want of breath even when the respirations are notably hurried. Cyanosis is often a prominent symptom. Double pleurisy with effusion occurs in some instances.

The shortest duration in the cases which I have observed was eleven days. It rarely exceeds two months. Although there is great interference with the respiratory function, asthenia predominates in the mode of dying.

The disease has no distinctive physical signs. The tubercles disseminated about equally in both lungs, do not occasion an appreciable dulness on percussion, nor the auscultatory signs of solidification. Some dry and moist bronchial râles, due to bronchitis, may be heard at different points, but these are not constant. The fact that physical exploration gives a negative result is to be taken into account in the diagnosis. This result excludes other pulmonary diseases which might give rise to the pulmonary symptoms, namely, lobar pneumonia, pulmonary phthisis, and capillary bronchitis. The basis of the diagnosis is the exclusion of these affections, and the fact that the symptoms point to some grave intra-thoracic and general disease.

The difficulty in the diagnosis relates chiefly to the differentiation from typhoid or typho-malarial fever. With these diseases acute miliary tuberculosis is apt to be confounded. The difficulty of this differentiation is considerable, if, as sometimes happens, cough, with expectoration, rapid breathing, dyspnœa, and cyanosis, are not as prominent as they are in the majority of cases. In order to avoid error in diagnosis, care should be taken to exclude typhoid and typho-malarial fever, from the absence of the diagnostic points embraced in the clinical histories of these diseases. In this connection it is to be noted that in some cases of acute miliary tuberculosis fever-heat ceases for a time before death.

The treatment of acute miliary tuberculosis may be dismissed with a very few words. The condition of the patient is hopeless, and all that the physician can do is to palliate symptoms and sustain the powers of life. This is one of the diseases in relation to which recovery is proof of an error in diagnosis.

CHAPTER IX.

BRONCHITIS.

Acute Bronchitis affecting the Large Bronchial Tubes—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute Bronchitis. Acute Bronchitis in Young Children. Bronchitis affecting the small Bronchial Tubes. Epidemic Bronchitis. Bronchitis with Fibrinous Exudation. Circumscribed Bronchitis. Chronic Bronchitis.

THE preceding chapters have embraced inflammatory diseases affecting the pleura and the pulmonary parenchyma. It remains to consider inflammation seated in the lining membranes of the bronchial tubes. Inflammation in this situation constitutes the disease called *bronchitis*. This, in its ordinary form, is the most frequent of the pulmonary inflammations, and is a very common affection in all parts of the globe. A highly important

variety of the disease is based upon the size of the bronchial tubes affected. Generally the inflammation is limited to the large bronchial tubes. In an infrequent and much graver form the inflammation affects the small tubes. The latter form is usually, but, as will be seen, incorrectly called *capillary bronchitis*. Inflammation of the bronchial mucous membrane may be acute, subacute, or chronic, and varieties of the disease are based on these differences as regards the degree and duration of the inflammation. Bronchitis may be a complication of certain diseases, such as pneumonitis and phthisis, or it may not be preceded by any disease of the lungs. As a complication of other pulmonary affections, it is more limited than when it is the primary affection, and may be distinguished as *circumscribed bronchitis*. A form of the disease is characterized by the exudation of fibrin, and may be denominated *fibrinous bronchitis*. Finally, bronchitis characterizes an epidemic disease commonly known as *influenza*. These several varieties of the disease will claim separate consideration, after having considered the ordinary form, namely, bronchitis affecting the large bronchial tubes. The term *catarrh* has been used to denote inflammation of a mucous structure, giving rise to a mucous, or a muco-purulent, product. As the term bronchial catarrh expresses neither more nor less than bronchitis, it is superfluous, and may be dispensed with. Proceeding to treat first of ordinary acute bronchitis, it will be considered as occurring after infantile life, and, afterward, certain points relating to the disease as it occurs in young children will be briefly noticed.

Acute Bronchitis affecting the Large Bronchial Tubes.

Anatomical Characters.—Acute simple bronchitis begins with hyperæmia of the mucous membrane, often accompanied with little ecchymoses. The mucous membrane becomes swollen and soft. The congestive redness and the swelling apparent after death may be uniform in the affected tubes, or more marked in patches or zones. The appearance with respect to redness after death here, as in other situations, is not to be considered as evidence of the degree of hyperæmia present during life, for, in parts open to observation, for example, the conjunctiva, mouth, and throat, redness marked during life may diminish or even disappear after death. The inflammatory product consists of mucus, pus-corpuscles, and serum mixed with desquamated epithelial cells. Sometimes, especially in the early stage of the disease, the product is chiefly mucus when it appears translucent and viscid, at other times it is yellowish when it contains abundant pus-cells. A coating of muco-pus is found upon the inflamed mucous membrane after death.

In ordinary bronchitis the inflammation, as already stated, is limited to the large bronchial tubes. The tubes on both sides are equally affected, provided the affection be not incident to an antecedent pulmonary disease. With this exception, bronchitis exemplifies the law of parallelism; it is a bilateral or symmetrical disease. In this respect it differs from pleuritis and lobar pneumonitis.

Clinical History.—Acute bronchitis is generally preceded by inflammation of the mucous membrane of the nasal passages, or coryza. The inflammation commences in the nostrils and travels downward, either affecting, or passing by, the pharynx and larynx in its passage to the bronchial tubes. The period occupied in the passage varies from a few hours to one, two, or three days. In a certain proportion of cases, the bronchial tubes are attacked at once without any affection of the air-passages above. It is probably not correct to regard the affection successively of the nose, pharynx, larynx,

trachea, and bronchi as an extension of the inflammation from above downward, but as separate invasions from a common, internal determining cause.

The symptoms offer marked points of contrast with acute pleuritis and pneumonitis. Pain is not a prominent symptom, but the patient has a sense of constriction and of soreness or rawness. These painful sensations especially accompany acts of coughing. The pain is of an obtuse or contusive character, and is situated beneath the sternum.

The attack is rarely accompanied by a distinct chill, but chilly sensations, followed by flashes of heat, are frequently repeated during the career of the disease. The appetite may be more or less impaired, but is not usually lost. Lassitude is complained of, with a general feeling of malaise.

The pyrexia is moderate. The pulse has not the frequency and strength which it has in pleuritis and pneumonitis. The heat of the surface is not notably raised.

The cough is at first painful, but not sufficiently so to be suppressed. It is at first dry, the secretion of mucus being for a time scanty. Deep inspirations, breathing cold air, and the exercise of the voice excite acts of coughing, which occur in paroxysms, and consist of a deep inspiration followed by a series of expiratory efforts. If the paroxysms of coughing be frequent and severe, the traction of the diaphragm occasions pain and soreness referred to the false ribs and the ensiform cartilage. The patient feels as if a more abundant expectoration would give relief, and desires to have the cough loosened. The expectoration is at first small, glairy, frothy, and viscid, and occasionally streaked with blood. In the progress of the disease, after two, three, or four days, the expectoration becomes more abundant, and consists of thick, yellowish, or greenish sputa. The cough is then said to be loose, the acts of expectoration being easier, unattended by pain or soreness, and followed by a sense of comfort. The mucous secretion is rarely sufficient to accumulate in the tubes and occasion embarrassment of respiration. This may happen in young children, in the aged, and in feeble persons. The presence of a collection of mucus in the large bronchi or trachea is felt, and the patient is led to make voluntary efforts of coughing for its expulsion. The increased amount of the inflammatory products and the change in character, denote diminution or resolution of the inflammation.

Respiration is not sensibly affected. No portion of the lung is withdrawn from the exercise of its function as in pleurisy and pneumonitis. Dyspnœa is not produced save in the exceptional cases in which, from feebleness or the want of voluntary efforts of coughing, the mucous secretions accumulate sufficiently to obstruct the bronchial tubes.

The affection is not accompanied by much debility. Patients are generally not confined to the bed, and they may not confine themselves to the house.

The average duration of acute bronchitis is ten or twelve days. In severe cases, after five or six days patients are usually able to be out of doors.

The disease may be divided into two stages. The first stage embraces the period during which the expectoration is scanty, transparent, and viscid. The second stage extends from the time when the expectoration becomes abundant, opaque, and thick, to convalescence.

Pathological Character.—Acute, ordinary bronchitis is an inflammation affecting a mucous structure, leading to a secretion of mucus and the production of muco-pus in greater or less abundance. Resolution takes place in this situation without the occurrence of ulcerations.

Causation.—Primary or idiopathic bronchitis is supposed to be frequently, if not generally, produced by the action of cold. This is implied in the des-

ignation by which the affection is popularly known, namely, "a cold." Exposure to cold is supposed to produce this disease by interrupting the eliminative functions of the skin, whereby an increased duty is thrown upon the pulmonary mucous membrane, and by inducing internal congestion. This view of the causation is inconsistent with the fact that great exposure, in a large proportion of cases, is not followed by bronchitis, and also with the fact that in a large proportion of the cases of bronchitis it is not traceable to any unusual exposure. There is abundant evidence, however, to show that exposure of a portion of the body to a current of air is liable to excite an attack of this disease. In general it is reasonable to conclude that the disease is due to a morbific agent in the atmosphere or some special atmospheric change. This is, of course, to be inferred when the disease prevails as an epidemic; but it is a matter of common observation that a greater or less number of persons are apt to be simultaneously affected when the number is not enough to constitute an epidemic. Sometimes the occurrence of cases is connected with an obvious change in weather, but it would be useless to offer any speculations as to the particular atmospherical condition which stands in a special causative relation to the disease. The disease is more frequent in cold and temperate latitudes than in the tropics; and, in the former, it prevails especially in the spring and autumnal months. It offers a contrast to acute lobar pneumonitis which occurs oftener in warm than in cold climates.

Bronchitis occurs secondarily to, and forms an element of, other diseases. It belongs to the clinical history of rubeola or measles. In this connection it is frequently acute. It belongs to typhoid fever, but is rarely acute in connection with that disease. Developed in connection with diseases situated elsewhere than in the pulmonary organs, it is symmetrical, as when it occurs primarily; but, developed as a complication of pneumonitis and phthisis, it may be limited to one side, that is, unilateral, and is confined within a circumscribed area.

It may be produced traumatically by irritating gases received with the inspired breath. Inhalation of chlorine gas will produce it. I have known a severe attack produced by inhaling the fumes of sulphuric acid. In some persons, owing to an idiosyncrasy, the bronchial membrane becomes inflamed by constituents of inspired air which are innocuous when inhaled by most persons. The powder of ipecacuanha, emanations from newly-mown hay, and from feathers, the pollen of certain plants in the atmosphere during the summer and a portion of the autumnal season, and even fragrant odors, will produce bronchitis in those constituted with a peculiar susceptibility to these causes. Frequently, in these cases, to the bronchitis is added asthma, and this idiosyncrasy will be noticed in connection with the latter affection (*vide* Chapter X.).

As a rule, the liability to bronchitis is less in proportion as persons are habituated to free exposure in the open air. It is much more apt to attack persons who spend most of their time in warm apartments than those whose occupations keep them out of doors. Soldiers, surveyors, explorers, and hunters, who are accustomed to sleep at night in tents or in the open air, rarely "take cold," but it is a matter of frequent observation that, after having been for some time accustomed to camping out of doors, bronchitis occurs on resuming in-door quarters.

Diagnosis.—Acute bronchitis is to be discriminated from pleuritis and acute lobar pneumonitis, more especially the latter. The points relating to symptoms which are involved in this differential diagnosis, are as follows: the absence of lancinating pain, and the pain which is felt being sub-sternal; the presence of more or less expectoration which is not rusty, but either de-

void of blood or containing it in the form of streaks; absence of accelerated breathing and dyspnœa; absence of the circumscribed flush of the cheeks, the pre-existence of coryza with, perhaps, soreness of throat and subacute laryngitis. These points are chiefly negative, and they are not sufficient for a positive diagnosis in all cases, because the symptoms belonging to pleuritis or pneumonitis, which are wanting in bronchitis, are not uniformly present in cases of the two former diseases. The clinical history, however, and the results of physical exploration, render the diagnosis easy and positive.

The physical diagnosis is based chiefly on negative points. Percussion elicits the resonance of health. The vocal resonance is unaffected. The respiratory murmur may be weakened, but is not otherwise altered. Suppression of the murmur over a portion of the chest may occur temporarily from obstruction of a bronchial tube by an accumulation of mucus. These negative points warrant the exclusion of pleuritis and pneumonitis. The dry and moist bronchial râles may, or may not, be present at the time when the explorations are made. Their presence and diffusion, more or less, over both sides, are indicative of the existence of the disease, but the absence of the disease is not to be inferred because these signs are wanting when the chest is examined. They are oftener wanting than present, the conditions giving rise to the dry râles not existing, and the mucus in the bronchial tubes being too adhesive or thick to produce bubbling sounds.

Prognosis.—Acute ordinary bronchitis, not associated with other affections, is a dangerous disease only when it occurs in the young, aged, and feeble. The danger, in these classes of patients, arises from the accumulation of the products of inflammation within the bronchial tubes, and from the occurrence of collapse of pulmonary lobules or broncho-pneumonia (*vide* page 187). The danger relates to apnœa. The disease does not lead to great prostration and danger from asthenia. Exclusive of the classes of patients just named, it is generally a disease of little or no gravity. In the great majority of cases it passes through its course and the recovery is complete, but it may eventuate in chronic bronchitis. Associated with certain other affections, it may give rise to much suffering and danger. Occurring, for example, in patients affected with pulmonary emphysema, it occasions more or less dyspnœa, and it may prove fatal if the amount of emphysema be great. So in cases of spinal paralysis affecting the costal respiratory movements, the accumulation of the bronchial secretions, from inability to expel them by the action of the diaphragm alone, may occasion death by slow apnœa.

The disease has no tendency to induce either pleuritis or acute lobar pneumonitis, and, contrary to a general impression, it rarely precedes the development of pulmonary phthisis.

Treatment.—Acute bronchitis may be prevented, in some instances, on the appearance of coryza, by a full opiate and diaphoretic. A quarter of a grain of the sulphate of morphia, half a grain of codeia, a proportionate dose of any of the preparations of opium, or ten grains of either Dover's or Tully's powder, may be given for this object at bedtime, accompanied by a hot pediluvium and some warm stimulating drink, such as weak punch or toddy, or an infusion of some of the aromatic herbs, and followed in the morning by a saline purgative. If this plan of treatment do not succeed, it may mitigate the severity of the disease. A full dose of a salt of quinia (a scruple to an adult) will often act as a prophylactic, or, if given at once when the bronchial tubes become affected, as an abortive remedy. Twenty grains of salicin,

repeated once or twice after an interval of two hours, will be likely to prevent or arrest the disease. The Russian or Turkish bath is sometimes effective.

If the disease become established, it does not claim active measures of treatment, in view of the almost uniform tendency to recovery with mere attention to hygiene. Bloodletting is not called for except in some rare cases in which the patient is full-blooded, and the symptomatic fever unusually intense. Depletion by means of saline laxatives and reduced diet will generally suffice. If the attack be severe, confinement to the bed for a few days may be advisable in order to secure uniform warmth and moisture of the surface. Patients are more comfortable when moderately perspiring. In severe cases, an abundance of moisture in the apartment soothes the inflamed membrane, and renders the patient more comfortable.

Opium is thought by many to be contra-indicated in the first stage. It is supposed to interfere with the free secretion of mucus and to render expectoration difficult. This is an inference from the effect of opium on the secretions in health; but, so far from these results being produced, opium hastens the second stage. The free secretion of mucus is not the cause, but the consequence, of an abatement of the inflammation; and, by contributing to the latter, opium virtually acts as an expectorant. Opium, therefore, is indicated in the first stage of bronchitis, as it is in most acute inflammations. In the second stage, it is only indicated when the cough is out of proportion to the expectoration; that is, when the amount of cough is not needed to free the bronchial tubes. Opium is contra-indicated, if, owing to the feebleness of the patient, the efforts of expectoration are inadequate to prevent accumulation in the bronchial tubes. The inhalation of warm vapor, or spray, affords relief and promotes the secretion of mucus.

During the acute stage, if pain and soreness of the chest be prominent symptoms, sinapisms or stimulating liniments are useful. These symptoms do not claim blisters or other active measures of counter-irritation.

The stimulating so-called expectorants are not indicated in the first stage. In so far as they have the faculty of exciting the bronchial mucous membrane, they tend to increase the inflammation. They are rarely indicated in the second stage. If the affection linger and threaten to become chronic, the sulphate of quinia and other tonic remedies, together with a nutritious diet and an invigorating regimen, are the most efficient measures for recovery. I have been led by experience to regard the iodide of potassium and chlorate of potassa as useful remedies in both the first and second stage of acute, as well as of chronic, bronchitis.

Subacute Bronchitis.

The difference, as regards symptoms and therapeutic indications, between the acute and subacute forms of bronchitis, is such that a passing notice of the latter, under a distinct head, is called for.

Subacute bronchitis is, in common language, a slight cold, beginning usually with coryza, and running the same course as acute bronchitis, but with less severity, and perhaps not involving the same extent of the bronchial mucous surface. The affection is not of sufficient gravity to keep patients within doors, and, in the majority of cases, they do not call upon the physician, but either allow it to run its course, or resort to some domestic remedies.

This form of bronchitis may frequently be arrested; but, if not, it claims only a saline laxative, followed by a little anodyne, such as one-eighth of a grain of the sulphate of morphia or a quarter of a grain of codeia every four or six hours in syrup. It is not necessary to enjoin confinement within doors.

As it is desirable not to exaggerate, as well as not to depreciate, the importance of diseases, it should be understood, by physicians and patients, that common colds do not tend to eventuate in inflammation of the lungs, or in phthisis. A certain amount of care is advisable, and mild remedies are useful, but it would be injudicious to subject patients to active measures of treatment, or to needless precautionary restrictions.

Acute Bronchitis in Young Children.

Acute bronchitis in young children offers an important peculiarity in the greater liability to collapse of pulmonary lobules and broncho-pneumonia. (See page 187.)

Collapse of pulmonary lobules is incidental to bronchitis in young children, in consequence of the accumulation of mucus in the bronchial tubes. The tubes consisting of branching cylinders diminishing in calibre, it is easy to understand that plugs of viscid mucus, in certain situations, may obstruct the ingress of the inspired air into the air-cells, without obstructing the egress of air from the cells in expiration; hence, collapse occurs of the lobules to which the obstructed tubes are distributed. In expiration, the plugs are moved by the current of air from the smaller into the larger tubes, but in inspiration the current moves them into a position in which the progress of air is interrupted. It is supposed that collapse may occur when the current of air in expiration as well as in the act of inspiration is obstructed, the air which is thus pent up in the lobules being absorbed. In proportion to the number of collapsed lobules, the respiratory function is compromised, and danger from apnœa may attend this accident. It is more liable to occur in young children than in adults, because children do not promote expectoration by voluntary efforts, and also because the respiratory acts are less vigorous. It occurs especially in feeble children. It does not, however, belong exclusively to acute bronchitis in young children; it occurs in aged persons, and may take place in those of any age who are constitutionally weak. It is also incidental to chronic bronchitis in children and adults, and it enters, as will be seen hereafter, into the causation of emphysema of the lungs.

The occurrence of collapse of pulmonary lobules may be strongly suspected in the course of acute bronchitis, if the respirations become frequent, with dilatation of the alæ nasi, accompanied perhaps with lividity, and if the symptoms and signs of acute lobar pneumonitis be wanting. Physical exploration does not furnish definite signs of this accident. Relative dulness on percussion may be found on one side, if there be a marked disparity between the two lungs as regards the number of lobules which are collapsed. The respiratory murmur will be likely to be more feeble over the posterior than over the anterior portion of the chest, and, if relative dulness on percussion exist on one side, the murmur of respiration will be more feeble on that side. Mucous râles are more or less abundant.

In the treatment of bronchitis in young children, the liability to this accident is to be considered. Mild emetics are indicated with a view to promote the expulsion of mucus from the bronchial tubes. They are admissible because they occasion less disturbance than in adults. They are indicated because in young children the acts of coughing are for the most part purely reflex; that is, voluntary efforts to expectorate are not made. They should not, however, be repeated too frequently, and antimonial emetics should never be employed. Apomorphia, administered hypodermically, is recommended by some recent authors as an emetic and expectorant; but the grave effects which have sometimes followed small doses, render the use of this remedy of doubtful expediency, especially in young children. Remedies to maintain

nausea are contra-indicated on account of their depressing effect; an emetic should be given to produce prompt vomiting, and afterward nauseant remedies withheld, until a repetition of the emetic be deemed advisable. And, in the mean time, tonic remedies, a nutritious diet, and perhaps alcohol, are called for to support the general strength. Opium is to be given with great circumspection, since it may favor the accumulation of mucus in the bronchial tubes. The chief objects of treatment, in short, are twofold: *first*, to supply the want of voluntary efforts of expectoration by the judicious employment of emetics; and, *second*, by sustaining measures to maintain the force of the respiratory acts. The iodide of potassium, given pretty freely, has seemed to me to have a curative effect. Measures to excite deep inspirations, referred to in connection with broncho-pneumonitis (*vide* page 190), are to be included among the objects of treatment.

Acute Bronchitis Affecting the Small Bronchial Tubes.

An extension of inflammation from the larger and medium-sized tubes to those of small size, gives rise to the variety of bronchitis commonly called capillary bronchitis. This application of the term capillary is not strictly correct. The truly capillary tubes, that is, the ultimate subdivisions of the bronchial tree, or the bronchioles, are not the seat of inflammation in this affection. They are involved in pneumonitis. The bronchial branches of small size, but not the smallest, are affected in so-called capillary bronchitis. The larger tubes are generally first affected, and the small tubes become involved by a more or less rapid extension of the inflammation. The affection has within a recent period come to be understood, and has heretofore been known by various titles, such as catarrhus senilis, peripneumonia notha, bastard pleurisy, suffocative catarrh, etc.

This affection differs widely from ordinary acute bronchitis, as regards its clinical history and danger. It is an exceedingly grave affection, proving fatal, especially in young children, in a large majority of cases. The danger proceeds from obstruction to the current of air to and from the air-vesicles. The obstruction is incidental to the small size of the affected tubes; the swelling of the mucous membrane, and the presence of muco-purulent liquid, which, in the larger tubes, do not interrupt the free passage of air during the respiratory acts, here occasion serious interference, and, as the tubes in both lungs are affected, fatal apnœa is liable to be produced.

The anatomical characters, as regards the mucous membrane, are essentially the same as in bronchitis affecting larger tubes. The membrane is reddened, swollen, and softened, and the tubes are more or less filled with muco-pus which escapes in small drops when a section of the lungs is made. The obstruction from plugging of the tubes may lead to collapse of pulmonary lobules. Portions of the lungs are apt to become œdematous. Abnormal dilatation of the air-cells of the superior and anterior portions is another effect, and, in some cases, emphysema becomes developed in a great degree. This effect may be explained as follows: The forcible exertion of the respiratory muscles in labored breathing and coughing is brought to bear chiefly upon the lower part of the chest; hence, while the air is expelled from the lower portions of the lung, it accumulates in the upper portions, and thus occasions dilatation of the cells. This dilatation may be temporary, disappearing after recovery from the bronchitis. Although the inflammation reaches so near the bronchioles and air-cells, it never gives rise to acute lobar pneumonitis.

The mechanical obstruction, and the incidental circumstances just stated, afford an explanation of the symptoms which make up the clinical history of this variety of bronchitis; and, as regards its clinical history, it presents a

striking contrast to acute bronchitis limited to the larger tubes. The respirations are frequent in proportion to the severity of the case. In young children they may be increased to sixty or seventy per minute. Dyspnœa exists in a degree corresponding to the acceleration of breathing. In severe cases it amounts to orthopnœa, the patient keeping the sitting posture and suffering extremely for the want of breath. The speech is short and jerking; the alæ nasi dilate; the face is congested and swollen, and the countenance expresses anxiety and distress. Lividity is marked in consequence of imperfect oxygenation of the blood, and its accumulation in the right cavities of the heart. There is great restlessness. The pulse is notably frequent, but not accelerated in proportion to the respirations. Cough is more or less prominent, and is difficult and ineffectual from the want of breath. The expectorated matter coming from the small tubes does not contain bubbles of air; its specific gravity is greater than that of water, and it has sufficient consistence to preserve the form of the tubes. In its passage along the large tubes it becomes mixed with mucus from the latter, which contains air and consequently floats on water. The characteristic expectoration consists of mucus floating on water, with which are connected filaments sinking below the surface.

The symptoms distinguish sufficiently capillary from ordinary bronchitis, but they do not always suffice for the discrimination of this from other affections. It should never be confounded with laryngeal affections occasioning obstruction (simple or pseudo-membranous laryngitis), for in these affections the voice is affected, the cough is characteristic, and the respirations are labored, but not notably accelerated. Attention to the points just named will show the affection to be seated within the chest. The diseases with which it is most liable to be confounded are pneumonitis, asthma, and ordinary acute bronchitis with collapsed lobules. It may generally be discriminated from these affections by means of physical signs taken in connection with the symptoms. The resonance on percussion is not diminished in capillary bronchitis, and over the upper lobes it may be greater than in health, owing to an emphysematous condition of the air-vesicles. The presence of muco-purulent liquid in the small tubes gives rise to the subcrepitant râle. As the affection is bilateral, this râle is heard on both sides, and especially on the posterior aspect of the chest. The respiratory murmur is weakened. I have known the anterior, superior, and middle portions of the chest, in a young child, to become largely dilated, presenting the characteristic deformity of long-continued and great emphysema, this appearance disappearing after recovery.

Pneumonitis is to be excluded by the absence of the symptoms and signs diagnostic of that disease. Dulness on percussion, extending over one or more lobes, is wanting. Pneumonitis is generally abruptly developed, and is not preceded nor accompanied by bilateral bronchitis. It is rare for pneumonitis affecting but one lobe to occasion so much disturbance of the respiration as takes place in severe cases of capillary bronchitis. The crepitant râle, if it be present, denotes pneumonitis, and, if this affection exist and have advanced far enough for the subcrepitant râle to become developed, the latter is confined to one side only, except in the rare instances in which the pneumonitis is double. The temperature of the body is, as a rule, higher than in capillary bronchitis, the thermometer in the latter rarely showing an elevation above 102° Fahr.

Asthma generally is accompanied with little or no pyrexia. The respirations are not rapid but labored, the labor being especially marked in expiration. They are accompanied by loud sibilant and sonorous râles. It is a paroxysmal affection, the dyspnœa not persisting as in capillary bronchitis; and, unless the case happens to be one in which asthma is experienced for the first time, the liability of the patient to this affection is known.

The discrimination from acute bronchitis of the larger tubes with collapsed lobules or broncho-pneumonitis, is more difficult. The differential diagnosis must be based on the greater gravity of the symptoms, the clearness of the resonance on percussion, and the diffusion, over both sides, of the subcrepitant râle in cases of capillary bronchitis.

Broncho-pneumonitis may supervene upon capillary bronchitis, of course increasing the gravity of the local symptoms and the danger. A rise of temperature to 103° or 104°, renders this complication probable, but by no means certain, for, exceptionally, these temperatures are observed in cases of capillary bronchitis, without the pneumonic complication. The occurrence of the latter cannot always be ascertained by means of physical signs.

Pleuritis with large effusion may give rise to accelerated breathing, lividity, etc., but this affection is readily excluded by the absence of the signs denoting the accumulation of liquid in the pleural cavity.

Capillary bronchitis occurs especially in young children, and, next in frequency, in the aged, but it is occasionally met with in adults. It is always a disease of gravity, but particularly so at the two extremes of life. In young children and the aged, it proves fatal in a very large proportion of cases. It destroys life, in some cases, rapidly. I have known it to prove fatal in less than twelve hours after the symptoms denoted gravity of disease. The average duration in fatal cases in children is from three to five days. The duration is longer in adults, and the disease is much less grave after childhood and during middle age. In cases ending in recovery, convalescence becomes established after a duration varying from a week to two weeks. Happily, it is by no means a disease of frequent occurrence even in young children. In the mode of dying, apnœa predominates; and the progress toward a fatal termination is denoted by increasing lividity, the pulse becoming more and more frequent and feeble, the skin covered with clammy perspiration, the labor and frequency of the respirations, together with cough and expectoration, diminishing toward the close of life, from muscular prostration. Thrombosis, or the formation of a clot in the right side of the heart, is an occasional accident.

Treatment.—Bloodletting may be employed at the onset, under those conditions by which the employment of this remedy in other inflammatory affections is to be regulated. It is not admissible in young or feeble subjects, and in employing this or any other debilitating measure, the physician should not lose sight of the fact that it is important to economize the strength in order that the laborious efforts of breathing may be carried on for a length of time sufficient for the resolution of the disease. The danger and distress incident to the disease arise chiefly from the deficiency of fresh supplies of air in the air-cells; and if bloodletting be injudiciously practised, the patient suffers from the want of both blood and air. The importance of economizing strength should also enforce circumspection in the use of saline depletants and sedative remedies. These should not be pushed to the extent of producing prostration. The difficulty consists in mechanical obstruction which neither these nor any therapeutical measures will immediately remove. The safety of the patient depends on the maintenance of life until the disease passes through its career. The inhalation of oxygen affords marked relief of the dyspnœa. Breathing warm vapor is not only highly useful as a palliative measure, but it does not a little toward promoting resolution of the inflammation. It should form an important part of the treatment; and the most effective method is to keep the atmosphere of the room constantly and abundantly charged with steam during the course of the disease. Water in several vessels should be kept at the point of ebullition by means of heat in fireplaces,

stoves, or burning gas. The temperature of the room should be kept at a high point, 85° to 90°. The iodide of potassium should be given freely.

Emetics in young children are advisable for a reason already stated, namely, to supply the want of voluntary efforts of expectoration. Care, however, is to be taken not to repeat them so often as to occasion exhaustion. The use of apomorphia has been already referred to (page 233). Laxatives are useful by diminishing the contents of the intestines, and thereby giving space for more effective action of the diaphragm in respiration. Revulsive applications to the chest are useful, but blisters are of doubtful utility.

The great object being to carry the patient safely through the disease, supporting measures are early indicated, and they are important in proportion as the symptoms denote failure of the vital powers.

Epidemic Bronchitis.

For the last four or five centuries, medical observers have noted the occurrence, from time to time, of an epidemic affection characterized by bronchitis. In most countries it is commonly known by the name *influenza*, after a term introduced by the Italian writers in the seventeenth century. In France it is called *la grippe*. As an epidemic, it is remarkable for its extensive and rapid diffusion, sometimes extending, within a brief period, over many different and widely separated countries. During its prevalence a vast number of persons of all ages are simultaneously affected. In some epidemics the fatality has been large, but, in most fatal cases other affections are developed, especially the so-called capillary bronchitis and broncho-pneumonitis. The fatality is limited chiefly to the aged and to persons with feeble constitutions.

Influenza differs materially from ordinary acute bronchitis. The bronchial affection is not more intense, but, commencing usually with coryza, the inflammation is apt to extend to the frontal and maxillary sinuses, to the lachrymal ducts and conjunctiva, and into the Eustachian tube. Frontal headache is a prominent symptom. It is accompanied by more marked general symptoms than ordinary bronchitis, namely, chills, pyrexia, lassitude, debility, anorexia, etc. It is apt to end in free perspiration or with diarrhœa. The disturbance of the system is out of proportion to the pulmonary symptoms. It is a general, not a local, disease. The bronchitis is not idiopathic or primary, but the local expression of a constitutional affection. It is an essential fever, not merely a local inflammation with symptomatic febrile movement. It is a peculiar species of fever, running a brief career, with bronchial inflammation as its anatomical characteristic.

A special cause is involved in the production of this as of every other epidemic disease. The nature, source, and mode of action of the special cause are unknown. It has been attributed to ozone in the atmosphere by Schœnbein and others, to animalculæ by Holland, and to cryptogamic productions by the late Prof. J. K. Mitchell. The special cause doubtless exists in the atmosphere, but it is independent of appreciable atmospheric changes. This fact was exemplified in the Massachusetts General Hospital during the extensive prevalence of this epidemic in 1832. Nearly all the patients in the hospital were affected, although the wards were kept day and night at a uniform temperature. Being an infectious disease, the germ theory offers the most rational view of its etiology.

The disease is generally mild, but, as already stated, it is liable to lead to the development of local affections, other than bronchitis, and may in this way prove fatal. Gairdner's observations go to show that, during the prevalence of influenza, other diseases are usually severe, and that the rate of mor-

tality from all diseases is increased. The duration of an attack of influenza is from three to six days.

In the treatment of epidemic bronchitis the physician must not regard the fever as purely symptomatic. This error might lead to needless depletory measures. Bloodletting is rarely, if ever, required. In healthful, vigorous subjects, brisk purging has seemed to me useful. This should not be resorted to if the patient be feeble or advanced in years. Aside from purgation, diaphoretic remedies and opium will meet the therapeutic indications. Associated affections claim appropriate treatment, but debilitating or depressing measures are to be employed with greater circumspection than if the affections were primary. In aged and feeble persons, tonic and supporting measures may be highly important.

Bronchitis with Fibrinous Exudation.

A variety of bronchitis is characterized by a fibrinous exudation on the inflamed mucous surface. This characteristic feature is expressed by the names diphtheritic, pseudo-membranous, plastic, croupous or croupal, which have been applied to it. It is frequently associated with inflammation of the larynx and trachea, attended with a similar exudation, constituting the affection known commonly as true croup, and occurring also in certain cases of diphtheria. But reference is here made to bronchitis with this peculiarity occurring independently of a similar affection of the larynx and trachea. Exclusive of the cases in which it accompanies croup and diphtheria, it is an extremely rare variety of bronchitis. The exudation is similar to that in the bronchitis secondary to croup. It forms a dense, membraniform layer which at first is closely agglutinated to the mucous surface, but sooner or later, loosened and detached by a suppurative process, is expectorated, if the life of the patient be sufficiently prolonged. When expectorated, the false membrane, as it is called, either has the form of patches or strips, or it is thrown off entire from portions of the bronchial tubes, and, when carefully displayed, may be found to consist of casts representing more or less of the bronchial subdivisions. Aside from the form of casts of the tubes, the fibrinous character of the expectorated matter may be ascertained by microscopical examination and by chemical reagents. It presents the fibrillæ which characterize exuded fibrin in other situations. Placed in a solution of acetic acid, it becomes swollen, whereas mucus contracts and is rendered more dense.

The fibrinous casts are expectorated in a globular mass enveloped in mucus, and, without close examination, they are liable to be overlooked. When the mucus is carefully removed, the casts, displayed in liquid, sometimes represent a bronchial stem of considerable size with subdividing branches which have extended to the smallest ramifications. These exudative casts are to be distinguished from those produced by the coagulation of blood within the tubes in some cases of bronchorrhagia. The latter do not, like the former, present laminæ or concentric layers, and they contain blood-corpuscles in greater or less quantity. They are, of course, preceded by hæmoptysis.

The inflammation in cases of bronchitis with fibrinous exudation, is either acute, subacute, or chronic. Occurring in young children, it may occasion sufficient obstruction to compromise seriously respiration, and it frequently proves fatal. Affecting adults, however, if not complicated with other grave affections, it rarely destroys life; and in the majority of cases the recovery is complete. I have met with a case in which it was associated with asthma and emphysema.

There are no symptoms or signs by means of which the diagnosis of this variety of bronchitis can be made out prior to the expectoration of false mem-

brane. When this occurs, the character of the affection is, of course, manifest. This expectoration is preceded and accompanied by violent paroxysms of coughing. It is followed by a muco-purulent expectoration which may be bloody. The symptoms are relieved by the removal of the fibrinous exudations or casts. The expectoration of the latter may be repeated after intervals of days, weeks, months, or even years. The character of the disease, if it prove fatal before the expectoration of false membrane takes place, may be suspected, but the symptoms and signs only show the existence of bronchitis with obstruction of bronchial tubes, and, perhaps, collapse of pulmonary lobules. This variety of bronchitis sometimes recurs repeatedly in the same person. A fine specimen of the bronchial casts was once sent to me from a distance, with the statement that the patient, a young girl, had had a considerable number of attacks, and, judging from this fact, other specimens could be had if desired.

The principles of treatment are essentially the same as in cases of acute or chronic bronchitis without this peculiar feature, and need not be separately considered. Warm vapor, or spray, inhaled, will aid in the separation of the false membrane.

Circumscribed Bronchitis.

As already stated, bronchitis, when circumscribed, is incidental to some other pulmonary disease. It is developed in pneumonitis, being limited to the lobe or lobes affected, and is the chief source of the expectoration in this disease if it do not go on to the suppurative stage. It occurs in pulmonary phthisis, and is limited to the tubes in proximity to the seat of the deposit of tubercle. The bronchitis, in this disease, furnishes the expectoration prior to the softening and discharge of the tuberculous product. As thus developed, bronchitis claims no special attention in a therapeutical point of view.

Chronic Bronchitis. Fetid Bronchitis.

Chronic bronchitis may follow the acute form, or it may be subacute from the beginning. It is far less frequent than acute bronchitis. It occurs much oftener in aged persons, than during the early and the middle period of life. It is associated especially with asthma, pulmonary emphysema, and cardiac disease.

The hyperæmia is less intense than in acute bronchitis. The color of the mucous membrane may be bluish-red, or it may be grayish or slate-colored. The morbid products upon the membrane are similar to those in acute bronchitis, but with greater predominance usually of mucus. More extensive changes, however, may occur in the bronchial wall. This, on the one hand, may become thickened by the development of new connective tissue, or it may become thinned in consequence of atrophy of the connective tissue and muscular fibres. With the production of new connective tissue, little papillary excrescences are often formed upon the mucous membrane. In consequence of loss of elasticity of the bronchial wall from destruction of its elastic fibres, in some cases there results dilatation of the tubes or bronchiectasis. The pulmonary tissue immediately surrounding a dilated bronchus is usually indurated by increase of the interstitial tissue. Three forms of bronchiectasis may be distinguished, namely, the cylindrical, the fusiform, and the sacculated. Bronchiectasis may accompany simple chronic bronchitis, but it is more apt to be produced when the bronchitis is associated with some affection giving rise to dyspnœa, such as emphysema, old pleuritic thickening with adhesions, fibroid phthisis, etc.

The symptoms relating directly to the bronchial inflammation, are essentially the same as in acute bronchitis, differing only in intensity, but connected with these symptoms, frequently, are others proceeding from associated affections.

Pain is generally wanting, or the patient complains only of a sense of uneasiness or constriction beneath the sternum. If cough be frequent and violent, soreness may be felt at the base of the chest on both sides, or at the epigastrium, due to the traction of the diaphragm on the ribs. Febrile movement is slight or wanting. A slight exacerbation of fever at night is observed in some cases. The appetite may continue good, or it may be more or less impaired. The nutrition is frequently not much, if at all, affected. The loss of weight, with the continuance of the disease, is not marked as it usually is in cases of pulmonary phthisis. The patient usually does not present pallor or a notably morbid aspect.

More or less cough always exists. In frequency and severity it varies much in different cases. It is paroxysmal, violent, and difficult in proportion to the small quantity and tenacity of liquid products within the affected tubes, and in proportion as the smaller tubes are involved. The expectoration also varies much in different cases. It is sometimes abundant, consisting of mucus with serous transudation. When the latter is copious, the affection has been called *bronchorrhœa*. It may consist of large, solid, greenish or ash-colored sputa, and in some cases small pearl-like masses are raised after much coughing; in cases characterized by the latter, the disease has been called, after Laennec, *dry catarrh*. The sputa may at times be streaked with blood. In general, the expectoration is muco-purulent, the purulent characters not infrequently predominating, and sometimes it appears to consist of pure pus. Formerly it was thought to be highly important to determine whether the expectoration was purulent or not, the presence of pus being supposed to denote something more than bronchitis. This is now deemed a point of comparatively little importance, since it is ascertained that pus is formed on a mucous surface. A very copious expectoration of pure pus, however, does point to some other source than bronchitis, such as the discharge of a tuberculous abscess, the third stage of pneumonitis, abscess of liver evacuating through the lung, empyema with perforation, etc. The diversified characters which belong to the expectoration in different forms of the disease, are of less value, in a diagnostic view, than was formerly supposed, since the knowledge which has been acquired of physical signs furnishes a far more reliable source of information respecting intra-thoracic conditions. The obvious differential characters by which mucus and pus may be distinguished from each other are as follows: Mucus is transparent or semi-transparent; it is more or less viscid; it is stringy and not miscible with water; it retains bubbles of air and consequently floats on water. Pus is opaque, less viscid than mucus, miscible in water, and in water sinks to the bottom. These differential characters are combined in varying proportions when the matter of expectoration is muco-purulent.

The matter of expectoration in some cases of chronic, as also of acute, bronchitis is notably fetid, having the characteristic odor of decomposed animal substances. The affection is then said to be *fetid bronchitis*. Generally, this characteristic fetor denotes either gangrene of lung, bronchitis with dilated bronchial tubes, or decomposition of matter within phthisical cavities; but it may occur independently of either of these conditions. Gangrene may be excluded by the absence, on microscopical examination, of any appearance of expectorated pulmonary tissue, and dilated tubes by the absence of the signs of that physical condition. The diagnosis is to be made by excluding these diseases, together with pyothorax and perforation of lung, the expecto-

ration in the latter sometimes having a notable degree of fetor. The explanation of fetid bronchitis is that, in rare instances, circumstances pertaining to morbid products within the tubes are favorable for the action of the putrescence-producing agents (germs) derived from the atmosphere.

Chronic bronchitis, of course, involves the same causes as the acute in the cases in which it is preceded by the latter. It may be produced and maintained by the inhalation of irritating particles of stone or metal in the exercise of certain occupations. Its continuance, in some cases, is referable to organic affections of the heart, consisting of obstructive or regurgitant mitral lesions. These act by inducing pulmonary congestion. It is an affection incidental to old age, occurring without any obvious causative agencies. It occurs in youth and middle age, irrespective of apparent causes, and is often associated with asthma and emphysema. To these affections it stands in the relation of a cause rather than an effect. In cold latitudes it is sometimes manifestly dependent on climatic causes, recurring with each successive winter, and disappearing during the summer season, or on removal to a warm climate.

It is not an affection which tends directly to destroy life. In the aged it may sometimes dispose to the development of capillary bronchitis, and thus, indirectly, prove serious. In connection with the feebleness of advanced years, it may lead to collapse of pulmonary lobules, and, in this way, shorten life. Its existence in a patient prostrated with any other disease, involves danger from the accumulation of morbid products in the bronchial tubes. It may lead to the development of asthma and pulmonary emphysema, affections which, although not immediately dangerous, diminish the duration of life. Aside from these contingencies, the evil to be apprehended is the permanency of the affection. It is liable to become established, persisting for years, and, in aged persons for the remainder of life. The existence of chronic bronchitis does not involve an increased liability to the development of pulmonary phthisis, but, perhaps, the reverse.

The diagnosis of chronic bronchitis involves discrimination from pulmonary phthisis. This would be difficult, and sometimes impossible, were the investigation to be limited to the symptoms; hence, before physical signs were studied, these two affections were of necessity confounded. The importance of the discrimination is obvious in view of the great difference between the affections as regards prognosis. The differential diagnosis is to be based mainly on the absence of the symptoms and signs which are diagnostic of phthisis. In other words, it is concluded that the latter does not exist, from negative evidence, or reasoning by way of exclusion. The results of physical exploration, as just stated, are mainly to be relied upon, but the absence of symptoms which belong to the clinical history of phthisis is also to be considered, such as progressive, marked emaciation, hæmoptysis, and accelerated breathing. These symptoms are wanting in chronic bronchitis. The physical signs in this variety of bronchitis are the same as in the acute form, namely, the presence of dry and moist bronchial râles, the resonance on percussion and the vocal resonance unaffected, the respiratory murmur weakened and sometimes suppressed over a portion of the chest from temporary obstruction of bronchial tubes, but its characters, aside from weakness, unchanged.

The coexistence of pulmonary emphysema is to be determined by symptoms and signs diagnostic of this affection, which will be considered in the next chapter.

In the treatment of chronic bronchitis, bloodletting or other depletory measures are never indicated. The affection seldom exists under circumstances which render it desirable to lower the powers of life. Counter-irritation, by

means of croton oil or stimulating liniments, is sometimes useful. The diet should be nutritious but not stimulating, consisting of milk, eggs, fowl, fish, and farinaceous articles. Meat, however, is not to be interdicted if the system be enfeebled. Wine and alcoholics are to be avoided, except when measures to support or strengthen the system are indicated. Attention to the surface of the body is important. In a cold or variable climate, woollen or silk garments should be worn next the skin. An undergarment of buckskin or chamois leather, worn over light woollen or silk, affords, during cold weather, great protection, and saves the inconvenience of an undue quantity of clothing. The object is to secure uniformity of the temperature of the surface, and to maintain the functions of the skin.

Medicines may be employed with a view to palliation and cure. If cough be troublesome, exceeding that required for expectoration, soothing remedies are called for. Opium, however, is to be prescribed with circumspection, in the first place, lest the habit of using it be formed—a consideration to be taken into account in all chronic affections—and, in the second place, in feeble subjects, and under circumstances in which there may be danger from an accumulation in the bronchial tubes, serious consequences may follow blunting that sense of the presence of morbid products which induces acts of expectoration. Moreover, the use of opium tends to impair the digestive powers. For these reasons, other anodynes, such as hyoscyamus, conium, belladonna, and hydrocyanic acid, are generally to be preferred.

As a rule, the remedies which are called expectorants are not indicated. The nauseant expectorants do harm by their depressing effect, and by disturbing the appetite and digestion. The stimulant expectorants, such as squills, senega, etc., are of doubtful efficacy, and, if not useful, are more or less hurtful.

Certain remedies, however, sometimes exert a curative effect. The iodide of potassium (or the iodide of ammonium) is one of these, and, perhaps, the one most likely to be successful. Five or ten grains three or four times daily, may be given at first, and, before abandoning the remedy as useless, the dose should be increased to the limit of tolerance. This remedy is not always tolerated even in moderate or small doses, and it is by no means always successful, although large doses occasion no inconvenience. The muriate of ammonia is in some cases a curative remedy. I have known it to effect a prompt cure, the disease having existed for ten years. The chlorate of potassa, half an ounce of a saturated solution given twice or three times daily, in some instances, proves highly useful, and may effect a cure. The balsam of copaiba is a remedy, the value of which, in this disease, is not generally appreciated. It has no value in certain cases, but its curative effect is sometimes so marked that it would seem to be almost a specific remedy. The spirits of turpentine occasionally prove equally efficacious. A good method of giving the latter is in what the late Prof. Clark, of Boston, called the continuous dose, namely, a drop in an emulsion every one or two hours throughout the day. Other balsamic remedies, the balsams of Tolu, Peru, sandal wood, are among the curative remedies, to which are to be added tar and the compound tincture of benzoin. The bromine salts are to be mentioned as useful remedies. This list might be extended. As an illustration of the great number of remedies which have been found useful in bronchitis, the National Dispensatory enumerates under this head one hundred and twenty-two articles.

Frequently, marked benefit, as regards the bronchitis, is derived from tonic remedies in conjunction with measures to invigorate the system. The salts of quinia and the preparations of iron are often highly useful. These and other tonic remedies are indicated if the powers of the system be reduced, or

the patient be anæmic. A generous diet is to be conjoined, and wine or alcoholics may be taken moderately with advantage. Out-of-door life, in such cases, should be added. This plan of treatment is applicable to a pretty large proportion of the cases of chronic bronchitis; to improve the general health, and restore vigor, are important objects in the treatment of this, as of any chronic local affection.

It is an object of treatment, in some cases, to diminish the amount of expectoration when this is excessive. For this end, astringent remedies may be prescribed, such as tannic acid, the persulphate or pernitrate of iron, and the preparations of zinc. After a bronchitis, however, has become habitual, especially in the aged, it sometimes appears to be, as it were, an element of health. At all events, patients complain of the discomfort arising from the suspension or diminution of the expectoration, and, for this reason, opiates do not procure relief. Under these circumstances, expectorants are useful as palliatives.

The inhalation of the spray from medicated liquids, produced by an atomizer, may be resorted to for several objects. A solution of the astringent remedies just named may sometimes be useful as a topical application in the form of a spray, with a view to diminish profuse expectoration. Oftener it is an object to facilitate expectoration. Spray from a solution of the muriate of ammonia, gr. j to gr. xv to the ounce, is useful in this way. Opium and other narcotics brought into direct contact with the affected membrane may be of service by allaying the irritation which occasions troublesome, superfluous cough. The vapor of tar is a soothing application. In fetid bronchitis, antiseptic inhalations are indicated. For this object the vapor of the oil of turpentine, a solution of carbolic acid from gr. j to grs. iv to the ounce, in the form of spray, may be inhaled, or a similar strength of a solution of permanganate of potassa. The bisulphite of soda in scruple doses, given every two hours by the mouth, is an efficient antiseptic. Medicated spray is to be employed with care as regards the strength of the solutions atomized and the frequency or continuance of the inhalations, bearing in mind that remedies held in solution pass rapidly into the blood, and may produce toxical effects.

Change of climate is sometimes advisable. A removal from a cold and variable climate to a situation in which the temperature is mild and equable may be attended with marked relief, and perhaps lead to recovery. Benefit may be looked for especially in the cases in which there is either immunity from the disease or marked amelioration during the summer season.

CHAPTER X.

EMPHYSEMA OF THE LUNGS. ASTHMA. PERTUSSIS.

Emphysema of the Lungs. Interlobular or Interstitial Emphysema. Subpleural Emphysema. Vesicular Emphysema or Dilatation of the Air-cells — Senile Emphysema — Anatomical Characters—Clinical History—Pathological Character—Causation — Diagnosis — Prognosis —Treatment. Asthma—Clinical History—Pathological Character— Causation — Diagnosis —Prognosis—Treatment. Pertussis, Whooping Cough.

EMPHYSEMA in general signifies the presence of air in the interstitial connective tissue. In the lungs, however, it is necessary to distinguish two kinds of emphysema. In one form there is an escape of air into the interlobular and subpleural connective tissue. This form is analogous to emphysema in other situations, and is called *interlobular* or *interstitial emphysema*. The other, and the more common variety, is called *vesicular emphysema*, and consists in an abnormal accumulation of air within the air-cells, whereby they become distended and their walls often atrophied.

Interlobular emphysema arises from rupture of the air-cells, causing a communication between the latter and the interlobular connective tissue. This sometimes follows perforating wounds of the chest or injury of the lung by the extremity of a fractured rib. It may also result from violent paroxysms of coughing, especially when the lung has been previously affected with vesicular emplysema. Its favorite situation is the anterior border of the upper lobe. Just beneath the pleura little air bubbles, often arranged like rows of beads, can be seen in the course of the septa between the lobules. The air sometimes detaches the pleura so as to form air-blebs of considerable size. A sub-pleural air-tumor may be as large as an English walnut, or even larger. Bouillaud has reported a case in which an air-tumor existed as large as the stomach. It is important not to mistake for interlobular emphysema a post-mortem generation of gas in the interstitial tissue of the lungs as a result of decomposition, a condition not infrequently found after death. In rare cases the sub-pleural air-blebs rupture during life, and pneumothorax, with or without pleuritis, results. Another very rare occurrence is the passage of the air from beneath the pleura along the root of the lung into the connective tissue of the mediastinum, and thence into the subcutaneous tissue of the neck. In this way the emphysema may become diffused over more or less of the body.

Vesicular emphysema, and this is usually meant when the term pulmonary emphysema is used, may occur as an independent affection preceded or accompanied by chronic bronchitis. This is known as *substantive* or *idiopathic emphysema*, in distinction from *vicarious* or *symptomatic emphysema*, the latter terms being applied to an abnormal accumulation of air in the air-cells of certain portions of the lung when the penetration of air into other portions has been obstructed, as, for instance, by pneumonitis, tuberculous deposits, tumors, effusions in the pleural cavity, pleuritic adhesions, occlusion of the bronchi, etc. Vicarious emphysema does not necessarily appear in the immediate neighborhood of the obstructed alveoli. Like all forms of emphysema, it affects most frequently the anterior borders and the upper lobes of the lungs. When one lung is compressed or hepatized, the other is often emphysematous.

The names *acute emphysema* and *insufflation* are given to a dilatation of the air-cells frequently met with in the lungs of those who have suffered

from severe dyspnœa during the last days or hours of life. It is usually observed in the apices and the borders of the lungs. The air-cells may be dilated to twice their normal volume. The elasticity of the alveolar walls is impaired, but, in distinction from chronic emphysema, they present no evident structural changes. Acute emphysema or insufflation of the lungs accompanies chiefly acute diseases of the respiratory organs, or other diseases terminating rapidly with dyspnœic symptoms. It is due to repeated forced inspiratory efforts.

In a well-marked case of chronic vesicular emphysema the lungs are enlarged. Upon opening the chest they do not retract like healthy lungs, but remain in contact along their anterior borders, so that the pericardium may be covered. Their contractility thus is impaired. The diaphragm may be pushed down to the seventh or eighth rib, and the adjacent viscera correspondingly displaced. The heart is pushed downwards and backwards, and, in consequence of hypertrophy and dilatation of the right ventricle, which are usually present, extends further to the right than normal. The borders of the lungs are rounded and puffy; the emphysematous portions do not crepitate upon pressure or incision, as do normal lungs, but have a soft, cushiony feel. The imprints of the fingers remain a long time. The lungs appear in general pale, anæmic, and dry, but often present patches and striæ of black pigment. The dilated air-cells can be distinguished with the naked eye. The air-spaces larger than a pin's head are the result of rupture of the interalveolar septa and coalescence of the air-cells. Such air-spaces or blebs frequently attain the size of a pea, and they may be considerably larger. Large air-blebs, from the size of a pea to that of a pigeon's egg, sometimes project above the lung-surface, and may become so detached as to appear pedunculated. Upon microscopical examination, it is seen that the dilatation begins in the alveolar passages and infundibula. They become expanded, and the alveolar septa are less prominent. The alveolar walls are thinned, and finally become perforated, at first usually in their centres. The holes between the alveoli enlarge, the air-cells coalesce, so that, by continuation of the process, larger and smaller air-sacs are formed. The process appears to be a gradual atrophy of all of the elements composing the alveolar walls. The finer elastic fibres early disappear, the larger ones diminish in size and frequently rupture and the capillary network becomes coarser by obliteration of numerous capillary vessels. This destruction of numerous pulmonary capillaries is not attended with hemorrhage, as the vessels become impermeable before they disappear. The most important symptoms of emphysema are referable to this loss of pulmonary bloodvessels. A partial compensation for this disturbance of the pulmonary circulation exists in the anastomoses between the pulmonary and the bronchial and subpleural vessels. Fatty particles are often found in the alveolar walls, probably from fatty degeneration of the alveolar epithelium and of the capillary endothelium. An apparent thickening of the alveolar walls may result from their being compressed and crowded together by dilated air-vesicles. Rindfleisch, however, claims to have seen an actual hypertrophy of the smooth muscular elements which, according to him, exist in the alveolar walls. There is nothing in the pathological appearances of chronic emphysema which supports the view, otherwise not improbable, that a primary vice of nutrition in the alveolar walls antedates the development of the emphysematous condition in many cases. Substantive emphysema is most developed in the upper lobes and along the anterior borders of the lung, also along the lateral borders of the base of the lung; but it may be diffused over the whole lung-surface and in its substance. It is accompanied by chronic bronchitis which may either precede or follow the emphysematous condition. The bronchial mucous membrane is coated with

muco-pus, the bronchial wall may be thickened, and sometimes dilatations of the bronchi are present. In consequence of the obliteration of pulmonary capillaries there is obstruction to the flow of blood through the lungs, leading to hypertrophy and dilatation of the right ventricle, and frequently to venous congestion in the various viscera. Chronic congestions of the liver, spleen, kidneys, stomach, and intestines are present in severe cases. These conditions are similar to those met with in valvular lesions of the heart, and will be more fully described in that connection.

The emphysematous condition, especially in vicarious emphysema, may be limited to a few vesicles. Its practical importance, of course, depends upon the extent of lung involved.

A pathological condition of the lungs which bears little resemblance to true emphysema has received the name of senile emphysema. It is also called senile atrophy of the lungs. Here, instead of an abnormal accumulation of air in the lungs, these organs are smaller and contain less air than normal. In consequence of atrophy of the alveolar walls, the air-cells coalesce and form larger air-spaces. These, however, do not result from a dilatation of the alveoli, but from a gradual shrinkage and disappearance of the lung-tissue. These atrophic lungs are usually deeply pigmented, and take up less space than normal in the thoracic cavity. Senile atrophy of the lungs does not lead to hypertrophy of the right ventricle.

Emphysema, developed in a person free from tubercle, undoubtedly diminishes the liability to tuberculous disease. The two affections are rarely associated, exclusive of the cases in which pulmonary lobules in the vicinity of tuberculous deposits become secondarily emphysematous. In these cases the emphysema is vicarious. A reason for the protection against tubercle afforded by emphysema, may perhaps be found in the diminished quantity of blood within the emphysematous portions of lung, and in the fact that the portions affected with emphysema, namely, the upper lobes, are the primary seat of tubercle in the immense majority of cases. The condition of emphysema is, also, to some extent, incompatible with hæmoptysis. Pneumonitis, as a rule, is not developed in an emphysematous patient. I have met, however, several exceptions to this rule.

Clinical History.—Emphysema, existing to an extent to compromise considerably the respiratory function, is characterized by habitually labored breathing, and inability to take active exercise without suffering from want of breath. The laborious breathing is manifested especially in expiration. The rhythm of the respiratory acts is altered; the inspiration is shortened, and the expiration prolonged. As chronic bronchitis generally coexists, cough and expectoration are habitually more or less prominent as symptoms. The cough is usually violent, paroxysmal, and is characterized by a series of prolonged, spasmodic expiratory efforts, as in whooping-cough. The expectoration varies much in different cases as regards quantity and character. The acts of expectoration are difficult, and the sputa are frequently accompanied by an abundant, frothy, serous liquid, resembling soapsuds. Not infrequently sputa streaked with blood are expectorated.

The affection is chronic, and unaccompanied by febrile movement. The pulse is feeble and the body cool. Owing to an accumulation of blood within the right cavities of the heart, the surface of the body presents venous congestion, and this, together with deficient oxygenation of the blood, may give rise to a cyanotic hue. In extreme cases lividity is marked. The paroxysms of coughing are accompanied with great congestion of the face and turgescence of the cervical veins. Symptomatic phenomena aside from those referable to

respiration and circulation, are accidental. The appetite and digestion may not be notably impaired; the body, for a considerable period, may be well nourished, but, after a time, slow, progressive emaciation takes place. The countenance has an expression of distress which, conjoined with tumidity, and a dingy or livid hue, renders the physiognomy somewhat characteristic. At an advanced period anasarca may occur as a consequence of dilatation of the right side of the heart. Albumen in small quantity may be found in the urine, this being an effect of congestion of the kidney; and congestion of the liver and spleen may render these organs appreciably larger than in health.

These symptoms accompany the affection when it exists to an extent to compromise considerably respiration. Existing in a moderate or slight degree, there is no habitual want of breath nor labor of breathing. But the respiration is disturbed by active exercise; the patient is short-winded on attempting to run or walk fast, and this difficulty is apparent, also, in speaking, singing, and especially in paroxysms of laughter. Cough and expectoration are usually present, having the same characters as when the affection exists to a greater extent, but less marked. Congestion, tumidity, and lividity are present, not habitually, but during paroxysms of coughing or any violent physical exertion. The functions of the body generally may present little or no disturbance. Different cases exemplify all gradations between the two extremes, as regards the symptoms belonging to the affection.

Many persons affected with emphysema are subject to paroxysms of labored respiration and dyspnœa, which are due to another affection, namely, asthma. Acute ordinary bronchitis, occurring in a person affected with emphysema, occasions symptoms of embarrassed respiration, which do not belong to the clinical history of bronchitis occurring in a healthy person. The reason of this is to be found in the pathological character of emphysema.

The development of emphysema is generally slow. In the majority of cases, the previous history shows the commencement of the affection, as indicated by deficiency of breath on exercise, to be dated back many years, frequently extending to childhood, and not unfrequently beyond the recollection of the patient. Exceptionally, it may be developed with rapidity. Notable temporary emphysema occurs in paroxysms of asthma, and in cases of capillary bronchitis. The affection has no fixed duration, usually continuing, and progressively increasing, during the patient's lifetime.

Pathological Character.—Exclusive of the senile or atrophic variety, emphysema involves permanent dilatation of the air-cells, with, frequently, more or less destruction of the cell-walls and coalescence of the cells. In so far as destruction of air-cells takes place, it is obvious that the area of the respiratory surface is diminished, and the function of respiration in this way compromised. The dilatation of the cells involves a loss of the elasticity of the lungs, so that the accumulation of air within the cells offers an obstacle to the contraction of the chest in the act of expiration. Consequently, the air in the cells is not sufficiently renewed for the purpose of respiration; the air stagnates in the cells. In this way the affection compromises the respiratory function. The distension of the cells involves pressure upon the terminal branches of the pulmonary artery, and in this way the pulmonary circulation is obstructed. This obstruction is further increased by diminished respiratory function. The obstruction to the pulmonary circulation occasions an over-accumulation of blood in the right cavities of the heat; hence the venous congestion of the face and neck, and, to a greater or less extent, of the surface generally, with, in some cases, cyanosis. Hence, too, sooner or later, supervenes dilatation of the right side of the heart.

The pathological character of emphysema furnishes an explanation of the symptoms which make up the clinical history of the affection. When the respiratory function is so far compromised that the functional capacity of the lungs is insufficient while the respiratory acts are performed without effort, want of breath is felt and the respiration becomes labored. But if the emphysematous condition be slight or moderate, no difficulty is experienced habitually, because there is still functional capacity enough for ordinary respiration. The quantity of lung in health exceeds the amount required; there is a reserve provided for any unusual demand on the respiratory function, as in muscular exercise. If, therefore, the extent to which the respiratory function be compromised do not exceed the amount of lung held in reserve, no difficulty is experienced, save when an extra demand is made on the function. Under these circumstances, exercise, which involves an extra demand, cannot be taken without the want of breath being felt. The patient, who is habitually using the lungs to their fullest functional capacity, is disturbed by any interference with respiration. Ordinary bronchitis, which in a healthy person only requires a little of the reserve lung to be brought into play (a fact of which the patient is not conscious), occasions, if there be no lung in reserve, difficulty arising from the slight diminution of the calibre of the larger bronchial tubes which is incident to this disease; hence, patients with emphysema existing to much extent suffer from dyspnœa and labored breathing in ordinary bronchitis. The cough in connection with emphysema arises from the co-existing bronchitis; and the difficulty of expectoration is in consequence of the impaired elasticity of the lungs, the expiratory efforts in coughing not being brought to bear readily on the contents of the bronchial tubes.

The venous congestion of the face and surface generally is due to obstruction caused by over-accumulation of the right cavities of the heart. The lividity is, in a great measure, due to the same condition, but in part, perhaps, to deficient oxygenation of the blood. The smallness and weakness of the pulse also proceed from an obstruction to the free passage of the blood through the pulmonary circuit.

Causation.—The mode in which dilatation of the air-cells is produced has given rise to much discussion. Laennec, who was the first to describe distinctly this lesion, attributed it to obstruction of the bronchial tubes from the products of bronchitis. Regarding the inspiratory act as more powerful than the expiratory, he supposed air to be forced through imperfectly obstructed tubes in inspiration, and to remain imprisoned in the cells in consequence of the want of sufficient expulsive force in expiration. The dilatation, according to this theory, is produced by the rarefaction of the imprisoned air by heat, and by the reaction of the force of expiration in coughing, etc., upon the cells already filled with air. This theory is certainly not tenable in view of the fact that, of the two acts of respiration, the expiratory is a third more forcible, and still more when voluntary and spasmodic efforts are brought to bear upon it. The more powerful the efforts of expiration, in coughing, etc., the less ought to be the liability of accumulation of air in the cells communicating with obstructed tubes. An explanation of the mode of production has been advocated by Gairdner, of Glasgow, which differs essentially from the theory of Laennec. Gairdner attributes the affection to obstruction of bronchial tubes incident to bronchitis. But he supposes that the obstruction from collections of plugs of mucus leads to collapse, instead of dilatation, of the cells which communicate with the obstructed tubes, in the manner already adverted to in the chapter on broncho-pneumonitis (page 187). The current of air in the act of expiration may remove the mucus from its situation in tubes of small size into larger tubes where the obstruction is less; but the effect of the inspired current

will be to carry it back from the larger to the smaller tubes, the mucous plugs thus acting like a ball-valve upon the orifice of a syringe, obstructing the entrance of air to the cells, but permitting the escape of air from the cells. Moreover, owing to the greater force of the expiration, the expired air may be driven past obstructions which arrest the current of air in inspiration. Collapse of more or less of the pulmonary lobules being thus produced, a larger amount of air enters the cells communicating with unobstructed tubes, and these cells become consequently dilated. The dilatation of cells, in other words, is supplementary to the diminished volume of the lungs due to collapsed lobules, and is produced, under these circumstances, in the act of inspiration. In support of this explanation, Gairdner states that observation shows the tubes connected with emphysematous lobules to be unobstructed, and that close examination of lungs affected with emphysema will show the traces of collapsed lobules. Moreover, experiments of introducing into the air-tubes in inferior animals foreign bodies, such as shot and wads of paper, have been found to lead to collapse of lobules connected with the tubes in which these bodies become lodged, and dilatation of lobules connected with other tubes. This explanation will account for the production of emphysematous lobules so frequently found in connection with tuberculous deposits, the latter inducing solidification and diminished volume of the portion of the lungs in which they are situated. The term *vicarious emphysema* expresses the fact that it is supplementary to diminished volume of lung.

There is reason to believe that by prolonged, forcible efforts of expiration, as in long-continued exertions at lifting or pulling, playing on wind instruments, glass-blowing, or in voluntarily blowing through a partially obstructed tube, in the manner which has been to some extent practised as a means of preventing and curing consumption, the elasticity of the lungs may be diminished and permanent dilatation produced. It is well known that the chest may be in this way considerably enlarged, and deficiency of breath on exercise is sometimes a result. Expiratory efforts thus may sometimes co-operate with collapse of pulmonary lobules in the causation of emphysema. The paroxysms of whooping-cough and the labored efforts of breathing in attacks of asthma may be more or less involved in the causation.

The mechanism of the causation of emphysema by expiration is as follows: During violent acts of coughing the glottis is contracted and offers an obstacle to the free escape of air, and the muscles involved in the acts of coughing exert their effect especially upon the inferior portion of the chest. Under these circumstances, the air, not escaping through the glottis, distends the upper lobes of the lungs, and this distension, often repeated, leads to dilatation of the air-cells in these lobes. This explanation accounts for the fact of the upper lobes being especially the seat of emphysema, and that the anterior portions of the chest, in some cases, project beyond the limits of a forced inspiration in health. It is obvious that this explanation applies also to the production of emphysema by forcible acts of expiration produced otherwise than in coughing. Accepting this explanation, the fact that physical signs show emphysema, as a rule, to be more marked in the left than in the right upper lobe, may be thus accounted for: In coughing and all forcible expiratory efforts, the lower portion of the chest is more contracted on the left than on the right side, owing to the presence of the liver on the latter side.

The force with which the distension of the upper lobe takes place in violent coughing, is appreciable by palpation over the clavicles and between the ribs in thin persons. It was strikingly exemplified in the case of Groux, in whom there was a congenital absence of a portion of sternum. Forcible bulging within this wall was produced by coughing and by voluntary strong expiratory efforts.

The inspiration theory, as set forth by Gairdner, suffices to explain vicarious emphysema, but the expiration theory seems necessary for the explanation of substantive or idiopathic emphysema. Something, however, in addition to violent expiratory efforts is requisite, in view of the fact that a comparatively trifling expiratory pressure will produce the affection in one person, while, in many persons, severe paroxysms of coughing, etc., continued for a long time, do not occasion it. This view is supported by another fact, namely, that heredity is involved in the causation. Giving proper weight to these facts, it may be assumed that in many, if not most, cases, a causative condition is some error of nutrition in the alveolar walls.

The diminution of the elasticity of the ribs and costal cartilages, incident to advancing age, favors the production of emphysema. This change involves diminished extent and force of expiration, with undiminished, if not increased, power of inspiration. The result is, when the chest is expanded in inspiration, the lungs already contain a surplus of air. The lessened elasticity of the lungs in old persons has the same effect, keeping the organs permanently expanded.

The fact that emphysema belongs among the hereditary affections was first established by the late Dr. James Jackson, Jr., of Boston, who found that in 18 out of 28 cases, one or both parents had been similarly affected. The affection may be developed at any period of life. In a large proportion of cases its commencement is in infancy or childhood. Its slowly progressive increase explains the fact that patients frequently attain to middle life before the affection has advanced sufficiently to occasion great inconvenience.

Diagnosis.—The symptoms described under the head of the clinical history render the affection probable when it compromises considerably the respiratory function. The probability is increased by the co-existence of asthma in a large proportion of cases. The physical signs, however, render the diagnosis positive; and when the affection is moderate or slight, the signs are indispensable to the diagnosis. If asthma be not associated, patients are often supposed to have phthisis by those who rely on the symptoms in making the diagnosis.

The enlarged volume of the upper lobes of the lungs, in certain cases of emphysema, gives rise to distinctive signs obtained by inspection. In the cases in which the characters of the "emphysematous chest" are strongly marked, the diagnosis may be at once made with the eye. The upper and middle thirds of the chest, on its anterior aspect, are expanded, and present a globular or barrel-shaped form. This projection extends from the summit to the sixth rib. The obliquity of the ribs is diminished, and the angle formed by the junction of the ribs with the costal cartilages is more obtuse than in health. The inferior portion of the chest is relatively and actually contracted. The dorsal spine becomes curved anteriorly. In extreme cases, these changes amount to a deformity which is highly characteristic. The superior costal respiratory movements are lessened, and in labored breathing the ribs and sternum are raised together, as if they formed a solid bony case. The lower anterior portion of the chest is contracted, and the soft parts above the clavicles and sternal notch are depressed in inspiration. The chest is drawn permanently upward by the sterno-cleido-mastoid muscles and the scaleni, so that the neck appears to be shortened. The upper part of the chest, during the act of expiration, is in the same condition as at the end of a forced inspiration. The intercostal depressions are usually strongly marked. The heart's impulse is frequently seen and felt in the epigastrium.

These visible changes are present in cases in which the emphysema exists to an extent to compromise considerably the function of respiration, and in

which the volume of the lungs is notably increased. The signs are more marked on the side in which the emphysema is greatest; this side being, in my experience, generally the left. If the emphysema be comparatively slight or moderate, the size, form, and movements of the chest will not be sensibly altered. An abnormal relative fulness, however, may be observed on one side below, and perhaps above, the clavicle, with deficient superior costal movement. This disparity of the summit between the two sides, as regards size and mobility, is to be distinguished from a similar disparity due to contraction of one side from phthisis.

Percussion elicits an abnormally intense resonance, the character of the resonance being altered. The vesicular and the tympanitic quality are combined, that is, the resonance is vesiculo-tympanitic. This vesiculo-tympanitic resonance is more marked on the side corresponding to the lung which is most emphysematous, that is, generally the left side. The exaggerated resonance being greater on one side, care must be taken not to consider the resonance diminished on the side in which it is least exaggerated. The pitch of the resonance is always higher on the side which yields the greater resonance, whereas, if the disparity be due to diminished resonance or dulness on one side, the pitch is higher on that side. That the resonance is vesiculo-tympanitic over the upper lobe on the side on which it is least marked, that is, usually the right side, may be shown by comparing this resonance with that over the lower lobe on the same side.

The murmur of respiration is weakened in proportion to the degree of the emphysema. If the affection exist to such an extent that the respiration is habitually labored, the inspiratory sound may be shortened (deferred) and the expiratory sound prolonged. The expiratory sound, however prolonged, is lower in pitch than the inspiratory, as it is in health. The changes in intensity and rhythm are the only modifications proper to emphysema. Not infrequently, over portions of the chest corresponding to parts of the lungs which are not highly emphysematous, the labored efforts of breathing evolve an exaggerated vesicular murmur. The weakness and alteration of rhythm are likely to be more marked on the side corresponding to the greater degree of the emphysema. Sibilant and sonorous râles, due to co-existing bronchitis or asthma, are often present in cases of emphysema.

The normal relation between the two sides, as regards vocal resonance and fremitus, continues. In some cases, owing to the displacement of the heart, the resonance on percussion within the præcordial region is abnormally clear.

In arriving at the diagnosis by means of the foregoing signs, it is to be considered that other affections, such as phthisis, pleuritis, pneumo-hydrothorax, are excluded by the absence of signs which should be found if these affections existed. The signs are also to be taken in connection with diagnostic points embraced in the clinical history, namely, the character of the cough and expectoration, the absence of marked emaciation, notwithstanding the duration of the pulmonary symptoms, and, in many cases, the co-existence of asthma.

In the foregoing account, reference has been had to the ordinary form of emphysema, namely, the form characterized by dilatation of the air-cells. The atrophic form, or senile emphysema, offers certain marked points of difference, especially as regards the physical signs on inspection. The size of the chest, instead of being increased, may be notably diminished. The obliquity of the lower ribs may be much greater than in health, leaving sometimes but little space between the base of the chest and the pelvis. The resonance on percussion may be diminished.

Prognosis.—Emphysema, even in the cases in which it is most marked, rarely, if ever, involves, in itself, immediate danger. It is not a fatal affection *per se*, but it diminishes the power of the system in resisting intercurrent or superadded diseases. It leads to dilatation of the heart, which further impairs the ability to overcome other diseases. But aside from danger to life, it is an affection which, if it exist to an extent to compromise respiration, incapacitates for physical exertion and renders life uncomfortable. Existing in a lesser degree, it is a source of much inconvenience and annoyance from the deficiency of breath on exercise.

In so far as it involves destruction ot cell-walls, and the coalescence of air cells, it is an irremediable lesion. And, in the majority of cases, the dilatation of the cells which takes place is permanent; the tendency, in fact, is oftener to increase rather than to decrease. I have known, however, marked improvement to take place, as shown by the physical signs. In a case in which the enlarged volume of the upper lobes was sufficient to give rise to the characteristic deformity in a marked degree, the improvement was so great that the chest nearly resumed its normal form. In so far, therefore, as the lesion consists in dilatation of the cells, it is not necessarily irremediable.

Treatment.—The treatment of emphysema has reference, first and chiefly, to the bronchitis with which it is generally associated. The object is to relieve, and, if possible, remove the bronchial inflammation. In proportion as the bronchitis is relieved, the condition of the patient is rendered more comfortable, notwithstanding the emphysema continues undiminished; the emphysema is less likely to increase, and it may undergo diminution.

With reference to this object, the measures to be pursued are those indicated in chronic bronchitis not connected with emphysema. The treatment, in fact, so far as this object is concerned, resolves itself into the treatment of chronic bronchitis, which has been considered in the preceding chapter. Trial should always be made of the iodide of potassium. The effect of this remedy is in some cases truly marvelous, but in other cases it produces little or no effect. It may not be amiss to remind the inexperienced practitioner that some persons cannot continue the use of this remedy in consequence of great irritation of the fauces; and I have met with an instance in which it always produced violent vomiting and general disturbance. The eruptions on the face, to which it frequently gives rise, are an annoyance which may be submitted to, if it exert a curative effect as regards the bronchitis. When the remedy is well borne, it may be continued, in moderate doses, for a long period without any unpleasant consequences. I have known it to be continued in five-grain doses, three times daily, for a year, the patient finding that, under its constant use, he was nearly free from all pulmonary symptoms. In this case the emphysema was notably lessened. The chlorate of potassa, the bromide of potassium, and the muriate of ammonia should also be tried if the iodide of potassium prove ineffectual. If these be unsuccessful, the various other remedies which experience has shown to be useful in cases of chronic bronchitis should be tried.

Tonic remedies, and the regulation of diet and regimen, with a view to invigorate the system, form an important part of the treatment. If these measures fail, change of climate, if practicable, should be advised.

As there is reason to believe that violent paroxysms of cough contribute to perpetuate and increase the dilatation of the cells, palliative remedies for this symptom are called for, provided the bronchitis, on which it depends, cannot be removed. The labored effects of breathing in paroxysms of asthma probably have the same effect; and if this affection co-exist, it is desirable, with reference to the emphysema, to relieve the paroxysms as speedily as

practicable. It is important for the patient to avoid, as far as possible, attacks of acute bronchitis, and when they occur they should be cured as quickly as possible. Flatulence of the stomach or bowels and constipation contribute to dyspnœa by mechanically interfering with the play of the diaphragm. They are to be avoided by a regulated diet and appropriate remedies.

Exercise, as far as it can be taken without inconvenience, is not to be interdicted; but exertions which induce labored breathing are to be abstained from. Prolonged efforts of expiration, as in public speaking, singing, and straining at stool, are to be avoided.

The treatment by inhaling compressed air and breathing into rarefied air is recommended by German authors as often beneficial and sometimes effecting a cure. It has thus far found little favor in this country. Its employment requires caution lest it do harm. There is abundant testimony by competent observers of its value in cases of emphysema.[1]

The affection distinguished as atrophic or senile emphysema admits of no permanent relief. Ethereal preparations and remedies to palliate dyspnœa, together with measures to support the system, comprise the treatment.

Asthma.

The term asthma, used in a properly restricted sense, is applied to a disease which has well defined symptomatic features, and which, in the opinion of most authors at the present time, has, as an essential pathological condition, obstruction of the smaller bronchi, caused by spasm of their muscular fibres. The term has heretofore been applied in a loose way to dyspnœa dependent on different pathological conditions. For example, it has been customary to call the dyspnœa dependent on diseases of the heart cardiac asthma. The true pathology of asthma, that is, of the individual or substantive disease, to which the term should be restricted, seems to me clearly that just stated, namely, bronchial spasm. All, however, do not so consider it, and other opinions will be noticed in connection with the pathological character of the disease. Asthma has no anatomical characters. It is true that, in the great majority of cases, pulmonary lesions are found after death, particularly those which belong to chronic bronchitis and emphysema; but this fact only shows the frequent co-existence of these affections with asthma.

Clinical History.—Asthma is essentially a paroxysmal disease. The clinical history will therefore consist of an account of the characters which distinguish asthmatic paroxysms, together with the laws of their recurrence, and the condition of health in the intervals.

A paroxysm of asthma may commence without warning, or it may be preceded by certain premonitions. The premonitions vary in different cases. Patients are able often to predict an attack for some hours before its occurrence, sometimes by a sense of drowsiness or heaviness, sometimes, on the other hand, by an unusual excitation of the mind, and again, by sensations, the signification of which they have learned by experience, but which are not easily described. The paroxysm may be slowly developed, that is, an hour or two, and sometimes a longer period, may be required for its full development; or the attack may be sudden, and the intensity quickly reached. It takes place, in the great majority of cases, during the sleeping hours, and generally in the latter part of the night, or very early in the morning.

The paroxysm is characterized by laborious efforts of breathing, prompted by a painful sense of the want of air, or dyspnœa. The patient is unable to

[1] *Vide* article by Hertz in Ziemssen's Cyclopædia, Amer. edition, vol. v.

lie down, but sits with the elbows on the knees, or resting on some solid support, the mouth open and gasping with each inspiration. The respirations are not increased, but may be less in number than in health. The inspiratory act is performed with a spasmodic effort, and the expiratory act is prolonged and accompanied with a wheezing sound. Speech is difficult from the want of breath, and words are uttered with interrupted efforts. Movements of the body are dreaded, and changes of position are made slowly. Cold air, from its density, affords relief, and the patient desires the windows to be opened, without regard to chilliness of the body. The face is pallid, and sometimes presents with the palor a cyanotic hue giving to the face a death-like appearance. Frequently, perspiration is profuse. Limpid urine, in great abundance, is passed frequently, especially at the commencement of the paroxysm. The pulse is small and feeble, due to an accumulation of blood in the right cavities of the heart, in consequence of obstruction to the pulmonary circulation. The surface of the body is cool or cold. The nostrils are widely dilated. The countenance denotes extreme anxiety and distress. A frequent symptom is an itching sensation under the chin, which the patient endeavors ineffectually to relieve by rubbing, and the same sensation is frequently felt on the sternum and between the shoulders.

Paroxysms differ in severity. A patient suffering from a severe paroxysm presents a spectacle more distressing than can be well imagined; to one not familiar with the disease, he appears to be on the point of death. The suffering is considerable even when the paroxysms are so mild as not to present to the spectator a picture of great distress. Their duration differs. They may continue for a few minutes only, or for several days. Usually, after continuing for a few hours, either partial or complete relief occurs. If the relief be complete, or nearly so, tranquil sleep follows, which is peculiarly sweet and refreshing. With the diminution of suffering there are usually cough and more or less expectoration. The expectoration is frequently small, consisting in some cases, of a few mucous pellets, semi-transparent, and of a jelly-like consistence. Cough and expectoration, if they have not existed prior to the attack, generally continue for several days afterward, unless the paroxysm has been very mild and brief. The expectoration is sometimes streaked with blood, and occasionally a true hemorrhage or hæmoptysis takes place.

The paroxysms recur after intervals varying greatly in duration in different cases. They recur in some cases with great regularity after a stated period, and in other cases the recurrences are extremely irregular. Some patients suffer from a diurnal recurrence, and it is remarked by Salter that in these cases the affection is almost always associated with bronchitis or disease of the heart. Recurrence regularly after the interval of a week or a fortnight is not uncommon. Women sometimes have attacks only at the menstrual periods. Some persons experience an attack annually, and it may occur either in the winter or summer season. Examples of the latter are cases of so-called hay asthma which will be noticed presently under another head. When the paroxysms recur irregularly, they are sometimes attributable to a particular exciting cause, but in other cases the reason of their recurrence is not apparent.

In the intervals, the condition varies, the variations depending on the existence, or otherwise, of associated affections. Asthma is not infrequently associated with persisting chronic bronchitis, and, under these circumstances, more or less cough and expectoration are habitual. Emphysema is also a frequent concomitant, and deficiency of breath on exercise, or constant dyspnœa in proportion to the amount of emphysema, characterizes these cases. The habitual dyspnœa in these cases is due to the emphysema, and

is not properly asthmatic. Dilatation of the heart is another affection, not infrequently co-existing, which may give rise to more or less dyspnœa.

Pathological Character.—The pathological character of asthma has been already stated in defining the term as applied to an individual disease. It is a neuropathic affection, tonic spasm of the bronchial muscular fibres being induced by a morbid excitation through the nervous system. The exciting causes of the paroxysms doubtless exert their effect through the excito-motory or reflex nerves. It is true that bronchitis generally exists at the time of the occurrence of the paroxysms, but bronchitis exists often enough without asthma; and cases occur in which the spasm takes place independently of bronchitis. In the latter cases, the affection has been distinguished as nervous asthma; but, with the pathological view just presented, asthma is always nervous, and these cases differ from the majority only in the absence of co-existing bronchial inflammation. It is probable that inflammation renders the muscular fibres more prone to spasmodic action, and, in this way, is involved in the production of the affection, but not constituting an essential part of it.

This view of the pathological character of the disease is believed to be substantially correct, but it is proper to state that opposing theories have been advanced by distinguished authors. Wintrich, Bamberger, and others, contend that bronchial spasm does not exist in asthmatic paroxysms, but that the disturbance of respiration is to be attributed mainly to tonic spasm of the diaphragm. This theory is based on the evidence of the diaphragm remaining depressed and immovable during an asthmatic attack, and on the fact that there is an abnormal expansion of the lungs, the latter being, as is claimed, inconsistent with bronchial obstruction. The increased volume of the lung will perhaps account for the fixedness of the diaphragm, assuming this to be a clinical fact. That a spasmodic obstruction of the bronchi should be overcome by expiration rather than inspiration, may be *à priori* reasonable, but this reason should give way before clinical facts. The dry bronchial râles which are undoubtedly present, forming a marked feature of the disease, demonstrate bronchial obstruction; and the complete disappearance of these râles, together with the symptoms of the obstruction, in some cases, as an effect of certain remedial agents, such as the inhalation of chloroform, is proof that the obstruction proceeds from spasm.[1]

A later theory by Weber (1872) attributes the obstruction in great part to a swelling of the mucous membrane in the smaller bronchi, from dilatation of the bloodvessels, caused by a vaso-motor nervous influence. This theory was advanced many years ago by Beau in France. It does not do away with spasm, but attributes to the swollen condition of the membrane a certain measure of obstruction. The theory is not devoid of substantial support from clinical facts. It is consistent with the frequent occurrence of more or less expectoration coincidently with relief of the asthmatic condition, and it serves to explain the not infrequent existence of obstruction, notwithstanding the employment of treatment for the relief of spasm. That it is a pathological element of the disease is highly probable; but that it is an effect of the bronchial spasm, as held by Biermer and Trousseau, is, perhaps, the most rational explanation of its occurrence.

The discovery by Leyden, by means of the microscope, of the presence of

[1] For a fuller exposition of the doctrine of Wintrich, the reader is referred to the article by Riegel in Ziemssen's Cyclopædia, Am. ed., vol. iv. For its refutation *in extenso*, *vide* paper by Biermer, Ueber Bronchial-asthma, in Volkmann's Sammlung klinischer Vorträge, 1870; see, also, the classical work by Salter.

octahedral crystals in the matter of expectoration, in attacks of asthma, is a clinical fact which may be found to have significance. Leyden attributes the bronchial spasm to the irritation caused by these sharp-pointed crystals. The substance of which they are composed is supposed to be analogous to mucine.[1] The same crystals are met with in chronic bronchitis unattended by asthma.

Causation.—The occurrence of asthma involves a peculiar susceptibility in the bronchial muscular fibres to take on spasmodic action. This susceptibility does not exist in all persons. It constitutes a predisposition to the affection which characterizes certain constitutions. The majority of mankind, no matter to what influences they may be exposed, never experience this affection. The predisposition may be transmitted by inheritance. Of those who become asthmatics, so large a proportion have had parents or progenitors who manifested the same peculiarity of constitution, that there must be admitted to be, in some cases, an inborn and inherited predisposition. The fact of its being congenital is also shown by the occurrence of the affection not infrequently in early childhood and infancy, independent of any appreciable external causes. Whether the peculiar susceptibility be always congenital, or whether it be acquired in a certain proportion of cases, it is impossible to say. That the affection frequently does not occur until after youth, and is sometimes deferred until old age, and that it follows some other pulmonary affection, such as whooping-cough, bronchitis, or measles (which is frequently observed), do not prove that it does not involve an innate peculiarity of constitution.

For the development of the affection, certainly in most cases, in addition to the predisposition, exciting causes are requisite. The exciting causes are various, and the facts with regard to these show, in some persons, a remarkable susceptibility to particular agencies which upon most persons produce no morbid effect. A striking illustration of an idiosyncrasy, in this regard, is the variety of the affection commonly called *hay asthma*. The emanations from newly-mown hay produce, in some persons, coryza, bronchitis, and asthma, and the latter affection may never occur save when produced by this particular cause. The term hay asthma, however, is applied to cases occurring exclusively during the summer season, although the exciting cause may not proceed from hay. We meet with persons who suffer, for a certain period during the summer months, with asthma, associated with coryza and bronchitis, and during the remainder of the year they are entirely free from the affection. Sometimes the annual visitations in successive years occur precisely on the same date, and the duration is always about the same. For example, a medical friend of the author is attacked early in September of each year with coryza and bronchitis, and subsequently paroxysms of asthma occur during the night. He continues to suffer from the former affections and the nightly recurrence of the asthma for six weeks. The affections then disappear, and, except during the period just stated, his health is excellent. Relief and exemption are obtained by removing, at the period when the affections occur, to a situation devoid of, and distant from, vegetation. On going to sea, the affections are sure to disappear after sailing a certain distance from land.

The affection known as "Hay Asthma," or "Hay Fever," first described by Dr. John Bostock, in 1819, under the name *Catarrhus Æstivus*, has been studied, as it occurs in the northern part of this country, by Dr. Morrill Wyman,[2] and more recently by Dr. Geo. M. Beard. The latter gives the

[1] *Vide* article by Riegel, op. cit.

[2] Autumnal Catarrh (Hay Fever). New York: Hurd & Houghton, 1872.

results of an analysis of 200 cases.[1] According to Dr. Wyman, there are two forms of annually recurring bronchial inflammation (catarrh) in persons with a peculiar idiosyncrasy. The first is often called the "rose cold," or "June cold," commencing in the latter part of May or early in June, and continuing until early in July. This corresponds with the affection known in England as "Hay Asthma" or "Hay Fever." The other form is called by Dr. Wyman *Catarrhus Autumnalis*, or Autumnal Catarrh. In this form the affection begins generally in the third or fourth week of August, and ends in the latter part of September or in October. It rarely, if ever, continues after the occurrence of black frost. Asthma occurs in a certain proportion of cases only. The local symptoms denote irritation and subacute inflammation of the nostrils and bronchial mucous membrane, together with some febrile movement, and more or less constitutional disturbance. The affection appears not to exist in the Southern States, nor in the colder regions of Canada. Dr. Wyman has collected a considerable number of cases showing that relief may be obtained by going to certain portions of the White Mountain region; also Mount Mansfield, in Vermont, one of the Green Mountains, and the Adirondac Mountains, in the State of New York.

Dr. Beard's cases show that the affection occurs in July, as well as in May, June, and August, but less often than in the latter months; also that the Southern States and Canada are not exempt from the disease, but that its occurrence is rare. It is a rare disease west of the Mississippi, either north or south. It is undoubtedly caused by the inhalation of some agent connected with vegetation, and probably this agent is the pollen from grass, flowers, and trees. The same cause evidently is not alike involved in all cases. The idiosyncrasy in some persons relates to emanations only in May or June, and in others only to those in August; and of those who have the predisposition, some are affected in a particular place at a particular time, and others at the same place and time are not affected. The vegetable emanations, therefore, must be derived from different sources. The discovery of the sources of the causation, in a certain number of cases, will not apply to other cases. Assuming the morbific agent to be the pollen from plants, the idiosyncrasy in different persons has relation to different plants. The fact that removal during the summer and autumnal months to certain situations, secures exemption from the disease to some and not to others, is thus intelligible. Dr. Beard's observations give evidence of heredity as involved in the peculiar idiosyncrasy.

A curious idiosyncrasy is exemplified in the author's personal experience. This consists in the production of coryza, bronchitis, and asthma by an emanation from feather beds or pillows. Repeated attacks on sleeping away from home, especially in inns and steamboats, had occurred before the source was discovered. All feather pillows and even feather beds do not furnish the special emanation, and the circumstances on which the latter depends I have not ascertained. The poisonous principle is not connected with the odor which is sometimes perceived. I cannot determine beforehand whether a strange bed will excite an attack or not. If the feathers be of the (to me) poisonous kind, shortly after retiring, labored respiration, cough, and wheezing commence, and progressively increase until I am obliged to get up, when the difficulty passes off in a few hours, leaving a little bronchitis which continues for a day or two. I have never experienced the least degree of asthma excepting as a result of an emanation from feathers.

Dr. Richard M. Crane, of Hagerstown, Md., has communicated to me a case under his observation in which attacks of asthma were distinctly traced to sleeping beneath a feather bed made of duck feathers. The cause was not

[1] Hay Fever, or Summer Catarrh. New York: Harper & Brothers, 1876.

ascertained until after four years of suffering from the affection. It had not existed previously, the patient being fifty years of age, and there was no return of the affection after an ordinary feather bed, made of geese-feathers, was substituted for the bed which furnished the causative emanation.

Inhalation of the powder of ipecacuanha in some persons produces similar effects. Several examples of this idiosyncrasy have been reported. On relating my own experience at a meeting of a medical society, on one occasion, a member of the society gave an account of a case in which the same effects were produced by an emanation from the body of the horse, so that the person was debarred from riding or driving on that account. I have recently heard of another case of this kind. Beard cites other instances. Salter gives several examples in his work on asthma. Asthmatic attacks are sometimes brought on by emanations from the bodies of other animals, as the cat, rabbit, etc.

In persons subject to asthma, the paroxysms are liable to be induced by a variety of exciting causes, but individual cases differ as regards a particular susceptibility to certain of these causes. In some cases the inhalation of dust is particularly apt to bring on an attack. I have known a patient especially susceptible to the dust of grain and that arising when carpeted rooms are swept. The fumes of burning sulphur are apt to produce asthmatic breathing in those subject to the affection. Indigestion, in some cases, proves an exciting cause oftener than anything else. Some can refer paroxysms frequently to constipation. Salter relates a case in which the application of cold to the instep was sure to provoke an attack. Mental emotions sometimes act as an exciting cause. Occasionally the paroxysms are habitually connected with the menstrual function.

In the great majority of the cases of asthma bronchitis coexists. In a certain proportion of cases the bronchitis is constant or habitual, and the frequency of the paroxysms depends in a measure on the bronchitis ; for if the latter affection be relieved or removed, the asthmatic attacks become less frequent. The susceptibility to the exciting causes of spasm is increased by the existence of bronchial inflammation. In other cases, the attacks of asthma occur whenever bronchitis, or a common cold, occurs. Finally, climatic influences are involved in the causation, for it is a matter of frequent observation that the same persons are much more liable to recurrences in some situations than in others. And it is also a matter of common observation with some asthmatics residing in a locality in which they are subject to frequent recurrences, that atmospherical changes are apt to induce an attack.

Asthma occurs more frequently in males than in females, the proportion being as two to one. In the majority of cases it is developed prior to twenty years of age. It occurs not very infrequently in infancy.

Diagnosis.—The diagnosis in well-marked cases is not difficult. The features of the asthmatic paroxysms are quite distinctive. First paroxysms occurring in young children may occasion some perplexity, but, with proper knowledge and care, the disease should not be confounded with other affections. Capillary bronchitis is distinguished by the frequency of the respirations, the acceleration of the pulse with more or less fever, and the diffusion over the chest of the subcrepitant râle. In asthma the respirations are not accelerated but labored, the pulse is not notably frequent, and the dry bronchial râles are abundant. The dyspnœa incident to diseases of the heart often goes by the name of asthma, but the breathing in this form of dyspnœa is not labored, especially the expiratory acts, and accompanied by wheezing, as it is in asthma, and it is more or less habitual. Moreover, heart-lesions adequate to the production of dyspnœa are determinable by physical signs. Asthma

and cardiac lesions, however, may be associated. If asthma have existed for some time, it is usually associated with emphysema, and this association is diagnostic; yet, it is to be borne in mind that emphysema, sufficient to occasion dyspnœa, which may become greatly increased with a fresh occurrence of bronchitis, may exist without asthma; in other words, the dyspnœa due to emphysema and co-existing bronchitis is not properly called asthma. In addition to the abundance and diffusion of the dry bronchial râles, the physical signs, during a paroxysm, are enlargement of the chest in its upper and anterior regions, with diminished respiratory movements, vesiculo-tympanitic resonance on percussion, and suppression of the respiratory murmur. I have met with instances repeatedly of laryngeal spasm having been considered as asthma. The differential points are, however, distinctive. In laryngeal spasm the inspiration is slow and labored. In asthma the labor and slowness are in the expiration. The former has been well termed inspiratory, and the latter expiratory, dyspnœa. Laryngeal spasm is accompanied by stridor referable to the larynx, and the latter moves up and down with inspiration and expiration. The dry bronchial râles and the other physical signs referable to the chest are wanting, if there be only laryngeal spasm.

Prognosis.—A paroxysm of asthma, however severe or protracted, involves no immediate danger to life. Formidable as may appear an attack of great severity, and intense as is the suffering, it is doubtful if a fatal termination ever took place. In view, however, of the suffering, the tendency of the disease to become confirmed, with an increasing liability to recurrences, its existence must be regarded as a great calamity. If the paroxysms be produced by a particular exciting cause which, being known, may be avoided, the disease imposes simply more or less inconvenience; but, when they are liable to be produced by various causes which cannot be guarded against, it is truly a grievous affliction; and it is calamitous, of course, in proportion to the frequency with which the paroxysms recur, and their severity.

Asthmatics are not infrequently long-lived; yet, that it may shorten the duration of life, cannot be doubted. The labored efforts of breathing in the paroxysms contribute to the development and increase of emphysema. During the paroxysms, also, the circulation through the lungs being impeded, the right ventricle and auricle are unduly distended with blood returned by the systemic veins, and hence the disease occasions dilatation of the right side of the heart. The chances of long life are lessened by these lesions. Moreover, if the paroxysms be frequent and severe, they can hardly fail to impair the vital powers and diminish the ability to resist other diseases. If asthma secure, to a certain extent, exemption from pulmonary phthisis and pneumonitis, this advantage is perhaps overbalanced by the fact that pneumonitis, when it does occur, is apt to prove fatal, and that the supervention of a severe attack of bronchitis may destroy life.

Treatment.—The management of asthma embraces, *first*, the treatment of the paroxysms, and, *second*, the treatment in the intervals.

During a paroxysm, the objects of treatment are to lessen the suffering and bring the paroxysm to an end as speedily as possible. The measures for these objects have reference to spasm as the essential pathological condition. The measures to relieve spasm are various, each of which proves efficacious in some cases and not in others. Frequently the past experience of the patient is the best guide as to the particular measure which will be most likely to afford relief. In cases of asthma unaccompanied by bronchitis, a full opiate is sometimes quickly and completely successful; but, in the larger proportion of cases, it will not succeed in cutting short the paroxysm, nor afford marked

relief. Of other narcotics, stramonium is one which should be tried. The usual mode of administration is to smoke the dried leaves or fibres of the root, either in a pipe or prepared as a cigarette. This measure in some persons acts like a charm, and may be confidently relied upon as a prompt and effectual mode of obtaining relief; but, in the great majority of cases, it either produces no effect, or merely mitigates the severity of the paroxysm. Assafœtida, dracontium or skunk-cabbage, and the Indian hemp are sometimes efficacious. The ethers, given internally, are to some extent useful as palliatives, and occasionally produce complete relief. Belladonna is sometimes signally efficacious, given as recommended by Salter and Ringer, namely, 10 minims of the tincture repeated every two or three hours, unless disturbance of vision be produced. The bromides in full doses sometimes afford marked relief. A paroxysm is sometimes made to abort by a full dose of quinia—from 20 to 30 grs. to an adult.

Marked relief is frequently obtained, and the paroxysm is sometimes cut short, by nauseant remedies, namely, antimony, ipecacuanha, lobelia inflata, and common tobacco. The two remedies last named are especially efficacious in a certain proportion of cases. The common tobacco will be more likely to be successful if the patient be not accustomed to its use. With a view to the relief of the spasm, these remedies need not be carried to the extent of producing vomiting; if not effectual when nausea is induced, it will be useless, if not injurious, to push them further. I have known a paroxysm to be arrested at once by bloodletting, but this is a measure too potent to be employed except occasionally in persons who are robust and full blooded.

The inhalation of the vapor of ether is often an effective measure of treatment. Not infrequently the paroxysms are completely controlled by it, the patient passing, in the space of a few moments, from a condition of great suffering into one of ease and comfort. These cases are among those which afford the most striking examples of the resources of practical medicine. The dry bronchial râles which, before the inhalation, were loud and universally diffused over the chest, sometimes disappear as soon as complete relief is procured by the inhalation, a fact proving conclusively the existence and the cessation of spasm. Unhappily this measure, like the others, is only efficacious in a certain proportion of cases. It should be tried always, provided there be no circumstances to contra-indicate it. The hydrate of chloral succeeds in a certain proportion of cases, but, in view of the possibility of alarming effects, it should rarely be resorted to. The inhalation of chloroform is often successful, but, in view of danger, ether is always to be preferred. The inhalation of the nitrite of amyl affords temporary relief, and in some instances arrests a paroxysm. Four or five drops may be inhaled from a handkerchief. The inhalation of compressed air is recommended by German authors. Trousseau found the inhalation of the vapor of ammonia useful in some cases. Duclos succeeded in sometimes arresting a paroxysm by the application of aqua ammoniæ to the fauces by means of a probang. Others who have made trial of this measure have found it in some cases to succeed, but in other cases to increase the dyspnœa.[1] Dr. Monell states that he has succeeded in obtaining relief in an attack of asthma by prolonging as far as practicable the expiratory act, then waiting as long as possible before inspiring, and retaining the air at the end of the inspiration as long as possible, this plan being continued for fifteen minutes. He states that he has repeatedly obtained immediate relief in this way, and that he knows of several cases in which the plan has proved successful.[2]

[1] A new remedy, the tincture of Quebracho, is recommended by Penzoldt and others in asthma and other diseases attended by dyspnœa.

[2] New York Med. Record, Aug. 15, 1866.

It is hardly necessary to say that if there be ground to suppose the attack to have been brought on by overloading the stomach or by constipation, an emetic or a cathartic is indicated. And, of course, the patient is to be removed from the action of any known exciting cause, such as the emanations from hay, feathers, etc The apartment should be large, high, and airy. Warm and stimulating pediluvia afford some relief. Strong coffee, taken hot, is generally useful as a palliative. Another palliative measure, which sometimes proves to be curative, is to be added. This consists in diffusing throughout the apartment the fumes of burning nitre-paper, that is, bibulous paper dipped in a saturated solution of the nitrate of potassa, and dried, or by burning pastiles prepared for that purpose. Some patients find great relief from this measure, and occasionally the paroxysms are arrested by it.

The treatment in the intervals has for its object prevention of the paroxysms. The removal of the predisposition would be the most effectual mode of accomplishing this object. This, however, is not to be expected, and the object is to be attained by measures having reference to circumstances which increase or act upon that susceptibility of the bronchial muscular fibres constituting the predisposition to the affection.

When, owing to a peculiar idiosyncrasy, paroxysms are excited by a particular cause, such as emanations from hay, feathers, etc., avoidance of exposure to the cause, if possible, is obviously indicated. It is doubtful if any remedy will produce insusceptibility to the action of the particular cause, or secure exemption so long as the exposure to the cause continues. In the cases of the so-called hay asthma which have come under my observation, a great variety of remedies have been tried, but all without much avail. The patient must either endure the continuance of the affection for several weeks, or he must seek a situation where he is not exposed to the exciting cause. Inasmuch as the cause of this variety of asthma enters the air-passages by the nostrils and occasions coryza before it reaches the bronchial tubes, the attempt has been made to neutralize it by topical applications within the nostrils. Liquid injections or atomized fluids have been employed for this purpose. Helmholtz found in his own person that a solution of quinia injected into the nostrils was preventive of effects other than the coryza, and this result has been obtained in some other cases. This treatment has, however, much oftener failed than succeeded. Experiments with other remedies have not furnished any striking results; but this plan of prophylactic treatment merits more attention than it appears as yet to have received.

In a large proportion of cases, the liability to paroxysms is more or less increased by the existence of habitual or chronic bronchitis. The relief or cure of the latter affection, in these cases, is the immediate object of treatment. The iodide of potassium or of ammonium should always be tried. I have known patients who were rendered comparatively comfortable, as regards the recurrences of asthma, by the use of this remedy. In small or moderate doses it may be continued indefinitely without any apparent injury. I have known from 5 to 10 grs. to be taken most of the time during four or five years, the patient finding that thereby he was protected against a recurrence of the paroxysms. The remedy will be useful in proportion to its curative effect on the bronchitis; it is, however, useful in some cases in which the co-existing bronchitis is slight, and when no apparent effect upon the latter is produced. The hydriodic acid has proved in some cases as effectual as the iodides. In the treatment of asthma, as of chronic bronchitis without asthma, the doses of the iodides may be gradually increased so as to amount to fifty or sixty grains per diem. The bromides are serviceable in certain cases, and they are well borne by some who cannot take the iodide of potassium without unpleasant effects. The chlorate of potassa is sometimes useful, and

the other measures indicated in cases of chronic bronchitis may be employed. The arsenical medication, that is, arsenic in small doses continued for a considerable period, has been found in some cases highly useful. The same is to be said of sulphur.

If measures addressed to the bronchitis prove ineffectual, or if the paroxysms recur when bronchitis does not co-exist, and they be not referable to particular causes which may be avoided, nothing is to be depended on but change of residence. And it is probable that most asthmatics may find some place in which they will be comparatively, if not entirely, free from the affection. Facts showing the immunity obtained by change of residence are remarkable as illustrative of an apparent capriciousness of this affection. Persons residing in the country often find relief by living in cities or large towns. A change from the most salubrious part of a city to a part where the atmosphere is smoky and insalubrious as regards the general health, sometimes secures exemption from the affection. A change of apartments from one story to another, or to a different exposure, has been known to prove effectual. I have known a patient to suffer nightly from a severe attack directly on the sea-shore, whereas the nights were passed comfortably a mile inland. There are no fixed laws with respect to the best climate or situation for asthmatics; each case has its own law which is only to be ascertained by experience. In commencing trials of change of residence, a place should be selected in which the climatic influences are the opposite of those belonging to that in which the patient resides; that is, if the residence be in the country, the city may be tried, and *vice versâ;* if on the sea-shore, an inland situation, and *vice versâ;* and so with regard to temperature, moisture, elevation, etc. The principle to be acted on is, that there is a place in which each martyr to this complaint will suffer less, and perhaps be entirely free from it, and the plan should be to make repeated trials until the desired spot is found. I could cite from the cases which have come under my observation several in which this plan has proved successful. It is to be enjoined, whenever practicable, as soon as it is evident that other measures will not secure the patient against the suffering incident to the frequent recurrence of the affection.

At the present time, in this country, the climate of Colorado is regarded as the most favorable for asthmatics. That residents in that climate are rarely affected with asthma, and that persons who suffer from the disease generally find relief there, cannot be doubted in view of ample testimony; yet it has happened to me to be consulted in the case of a boy about 12 years of age, who had suffered from the disease since early childhood, and who has recently come from Denver, where he had lived from birth. A brief stay, however, in Colorado or elsewhere secures exemption only during the time of sojourn; persistent relief requires a permanent change of residence. Hence, it is generally an object with patients to find some place where, aside from exemption from this disease, it is for their interest and happiness to dwell.

Pertussis—Whooping-Cough.

This affection belongs among the diseases of children, but it occasionally occurs after childhood and at all ages. In the cases occurring after adolescence, it is important that the physician be prepared to recognize it. The affection has no anatomical characters except those of ordinary bronchitis. Other morbid appearances found after death are due to complications which will be noticed in connection with the clinical history.

Clinical History.—The names of this affection derive their significance from certain characteristics pertaining to the cough. The first or the forming

stage embraces a period prior to the appearance of these characteristics. The primary symptoms are those of simple coryza and bronchitis. Frequently during this period there is nothing which denotes the affection to be other than a common cold. But, in the majority of cases, the cough is more violent, the acts of coughing persist for a longer time, and they progressively increase in duration and violence. There is also more or less febrile movement, which is more marked and continues longer than in ordinary bronchitis. At length the cough becomes distinctly, and in a marked degree, paroxysmal, and the distinctive features of the affection relate especially to the paroxysms. The duration of this first stage varies from one to two weeks. After the affection has advanced to the second stage, the patient is generally aware for a few moments previous to a paroxysm that it is impending. A child engaged in play suddenly is quiet, and the countenance expresses apprehension and distress. The morbid sensations are those of constriction, and an irritation in the larynx and trachea. These premonitions are sufficient to arouse the patient when asleep. The paroxysm is denoted by cough which is characterized by a series of violent expiratory acts succeeding each other so quickly that the patient is unable to take an inspiration between them. The number of these acts varies, according to the severity of the paroxysms, from six to twenty. A long and labored inspiration then takes place, giving rise to a crowing sound evidently due to spasms of the glottis; this is the whoop which enters into the name of the affection. Another series of coughing expiratory acts succeeds, followed again by the sonorous inspiration or whoop; and these alternate acts of coughing and whooping are repeated until the paroxysm ends. The contraction of the lungs by the spasmodic acts of coughing interrupts not only inspiration, but the pulmonary circulation, so that an accumulation of blood takes place in the right cavities of the heart. These effects are shown by notable congestion and lividity of the face and turgescence of the cervical veins. Tears flow in abundance. The suffering from dyspnœa is in proportion to the violence and length of the paroxysm. The contents of the stomach are frequently expelled; and at the close of the paroxysm more or less mucous secretion is expectorated. In proportion to the violence and length of the paroxysm the patient is fatigued or exhausted. However severe the paroxysm, there is scarcely any immediate danger either from apnœa or syncope. I have never known of an instance of death in a paroxysm. A medical friend, however, has related to me a case in which the breath was lost, and restored by resorting to the procedure known as Marshall Hall's ready method.

The paroxysms in different cases differ widely in severity, duration, the degree in which the characteristics are marked, and in frequency of recurrence. When extremely severe they occasion great distress, and serious incidental events are liable to occur. On the other hand, when quite mild they are comparatively trivial. Only one or two of the spasmodic expiratory acts may occur, or they may be repeated so that the paroxysm lasts for several minutes. The whoop is more or less loud and long in proportion to the amount of spasm of the glottis. Although generally present and marked, being, as the name implies, the most characteristic feature of the paroxysm, it is sometimes slight and sometimes wanting. In the latter case, the character of the disease has to be determined by other diagnostic features. A few paroxysms only may occur in the twenty-four hours, or they may recur during night and day at short intervals. They may amount to even a hundred within the twenty-four hours. In almost all cases they occur in greater number in the night than during the daytime, and in some cases they occur only at night. Exceptionally they are more frequent during the daytime. The paroxysms which occur in sleep are, of course, not produced by any obvious exciting

cause. This may be true of paroxysms occurring in the waking hours; but physical exertion and mental excitement, especially the latter, appear not infrequently to determine the occurrence of a paroxysm. Children are apt to experience a paroxysm whenever a fit of crying takes place. A patient is apt to have a paroxysm on witnessing a paroxysm in another patient, this fact illustrating the power of involuntary imitation.

Various events are incidental to the paroxysms, especially when the latter are severe. One of the most frequent of the incidental events is hemorrhage. Epistaxis is the most common form of hemorrhage. Not infrequently blood flows from the nostrils, in more or less abundance, with every paroxysm; and the loss of blood inducing notably anæmia, this favors the persistence of the hemorrhage. Hæmoptysis is an occasional form of hemorrhage. Blood sometimes escapes from the conjunctiva, or accumulates beneath this membrane. Trousseau cites a case in which a nævus situated on the face was the seat of hemorrhage with each paroxysm. Blood has been known to be forced from the ears. The primary and chief cause of the hemorrhage is the venous congestion arising from accumulation of blood within the right cavities of the heart. The urine and feces, or both, are sometimes expelled involuntarily during the paroxysm. Intestinal hernia is sometimes produced. Rupture of air-vesicles is an accident which sometimes occurs, giving rise to interlobular emphysema; and the air, finding its way along the areolar tissue connected with the primary bronchi and trachea, may produce emphysema of the neck and even extend over the entire body. Dilatation of the air-cells, or vesicular emphysema, is another incidental event. It is questionable whether this be not due to the bronchitis associated with whooping-cough rather than to the violent action of coughing; but the latter, doubtless, contribute to its production. When the paroxysms recur frequently, and are generally accompanied by vomiting, the system suffers from innutrition. Here is a source of anæmia in addition to the hemorrhages. Convulsions occur in some cases, especially in children, being attributable to the cerebral congestion occasioned by the venous obstruction at the right side of the heart.

In the intervals between the paroxysms, aside from complications or intercurrent affections, the general condition will depend on the frequency of the paroxysms, their severity, and the incidental events. The patient is enfeebled in proportion as the paroxysms are long, violent, and frequent, also in proportion to the amount of hemorrhage and the interference with nutrition by vomiting. The face is pallid in proportion to the anæmia. The veins of the neck furnish the venous hum, and the arteries a bellows murmur. Cephalalgia is a prominent symptom in some cases, arising from cerebral congestion. The febrile movement, which generally exists, in a greater or less degree, during the first or forming stage, as a rule disappears when the characteristic paroxysms are established, that is, in the second stage. If it continue into this stage, or if it be reproduced, it is due to an unusual intensity of the bronchitis, or to some inflammatory complication. The face is swollen or puffed, and this, with the pallor, renders the appearance quite characteristic. Certain complications are liable to occur, which add much to the gravity of the affection. Bronchitis is a part of the affection.

If the affection be uncomplicated, physical exploration of the chest elicits good resonance on percussion, with, perhaps, the dry or moist bronchial râles. The bronchitis in some cases is unusually acute, giving rise to fever and abundant mucous secretions. Collapse of pulmonary lobules and broncho-pneumonia are liable to occur in young children. The occurrence of vesicular emphysema has been already stated. The inflammation may extend into the minute bronchial tubes, giving rise to capillary bronchitis. This is denoted by the subcrepitant râle diffused over the chest, in conjunction with great frequency

of the respirations, notable acceleration of the pulse and lividity, the resonance of the chest on percussion not being diminished. Pleuritis with effusion is another complication more likely to occur in adults than in children. These several pulmonary complications are rendered severe and dangerous by the recurrence of the paroxysms of whooping-cough. Frequently the latter become less violent and frequent when any of the complications just named are developed; so that a premature improvement as regards the paroxysms of whooping-cough may be an unfavorable omen. When whooping-cough is accidentally associated with some acute disease, such as measles or scarlet fever, the paroxysms of cough, as a rule, become less frequent and violent; these intercurrent diseases interfere with the natural course of the affection. Finally, whooping-cough appears to determine the development of phthisis in some cases in which the tuberculous diathesis exists.

The duration of the affection is subject to considerable variation. Exceptionally the affection ends, of its own accord, in a few days. These cases are infrequent; but the fact that the affection is occasionally of short duration, when let alone, is to be borne in mind with reference to the supposed efficacy of remedies in abridging or arresting it. It is rare for the affection to end within a period of six weeks. In the majority of cases it continues for a longer period than this, and it sometimes persists for many months. As a rule, it gradually declines before it disappears, the paroxysms by degrees becoming less frequent and severe. Frequently, for a considerable period after the affection has ended, the characteristics are manifested, to a greater or less extent, whenever a bronchitis or common cold is contracted, or cough is excited by any cause. Trousseau states that the affection continues for a long or short period in proportion to the duration of the symptoms prior to the characteristic paroxysms; that is, if the latter are delayed the affection will be protracted, but if they are quickly developed the affection is not likely to last long.

Pathological Character.—This remarkable affection consists of three pathological elements. Bronchitis is one of these. This is the initial element. It is stated that this element is sometimes wanting, but examples must be exceedingly rare. Another element is fever. This is more or less marked in different cases, but is seldom wanting during the first or forming stage. The fever, as a rule, is out of proportion to the bronchitis, and is, therefore, to be regarded as not symptomatic, but idiopathic or essential. The most prominent of the three elements relates to the nervous system. This is manifested by the spasmodic expiratory movements in the paroxysms of cough, and by spasm of the glottis giving rise to the whoop. Some have considered the affection as belonging among the neuroses, others have considered it to be an essential fever, and by others it has been considered as a peculiar variety of bronchitis. It is neither of these separately, but collectively they constitute the affection. Dependent, as will be seen presently, on a special cause, the primary, essential pathological condition is general or constitutional, of which the bronchitis and cough are the local expressions.

Causation.—Whooping-cough is an infectious disease, and it is communicated by a contagium generated in the bodies of those affected with it. It probably originates in no other way. It is highly contagious, and few persons pass through childhood without contracting it. Young infants are liable to contract it. No period of life is exempt from susceptibility to the contagium. The infrequency of the affection after childhood is accounted for by the fact that the great majority of persons experience it before adolescence. Having been once experienced, the susceptibility thereafter ceases. This is the rule, but exceptionally the affection occurs more than once. The exceptions to the

rule as applied to this affection are not more frequent than to the rule as applied to other affections in the same category, for example, the eruptive fevers. The average period of incubation is not well ascertained. It is variable, the limits being one and two weeks.

Diagnosis.—When whooping-cough has advanced beyond the first or forming stage, and the characteristics pertaining to the paroxysms are well marked, it is recognized without difficulty. The whoop is a diagnostic criterion, but this is sometimes imperfect and even wanting. In these cases the diagnosis is to be based on the occurrence of paroxysms presenting the characters of well-marked whooping-cough, minus the whoop, on the duration of the affection, and on the fact of known exposure to the infection, together with knowledge of the fact that the patient has not already experienced the affection. The affection may be so mild and short that there is considerable doubt whether it has really occurred; but such cases are rare. It is desirable to make a probable diagnosis during the first or forming stage; that is, before the disease is fully declared by the characteristic paroxysms. It should be strongly suspected when cough and febrile movement are out of proportion to the bronchitis, and unduly persistent. Of course, the prevalence of the affection and known exposure are to be taken into account. Attention has been recently directed to the occurrence of ulcerations on either side of the frænum linguæ as a diagnostic circumstance. These are produced traumatically by the lower teeth, the tongue being partly protruded during paroxysms of cough. They occur only when, from the violence of the paroxysms, the diagnosis involves no difficulty. They are wanting, of course, in children before the period of dentition.

Prognosis.—Whooping-cough is rarely fatal *per se;* yet, indirectly, it leads to a considerable loss of life. Occurring in the course of other diseases —for example, measles, or during the ailments incident to dentition—it is apt to prove a serious affection. A fatal result is generally due to complications, the more frequent and important of which have been stated, namely, capillary bronchitis, broncho-pneumonitis, pleuritis, vesicular and interlobular emphysema, and phthisis. Young children, especially during dentition, are sometimes carried off by convulsions. As regards the affection itself, the gravity and danger are proportionate to the frequency and severity of the paroxysms, the duration of the affection, and the degree of anæmia and innutrition induced by hemorrhage and vomiting.

Treatment.—The treatment of whooping-cough embraces curative and palliative measures. It must be admitted that there are no known means by which the affection may be arrested. Measures are curative if they abridge the duration of the affection, or diminish notably its severity, and there are various remedies which possess more or less curative power.

Emetics were formerly considered as curative, given every other day for the space of a week or longer at the commencement of the affection. They were much extolled by Laennec, who preferred, as the emetic drug, ipecacuanha. Others have preferred the sulphate of zinc. Trousseau advocates, instead of the zinc or ipecacuanha, the sulphate of copper, given in solution, in small doses, according to the age of the patient, the doses being repeated at short intervals until vomiting is produced. In view of the testimony in behalf of the treatment with emetics, its efficacy in some cases cannot be doubted; but, owing to its severity, it is nearly or quite obsolete in this country. This method of treatment, it is to be borne in mind, is not admissible except early in the career of the affection.

Of other curative remedies, some are addressed to the bronchitis, and others to the neuropathic element. A combination of cochineal and the carbonate of potassa, commonly known as the cochineal mixture, has been much employed in this country. This mixture consists of cochineal, half a scruple; of carbonate of potassa, a scruple; of white sugar, a drachm, in four ounces of water. A dessertspoonful is to be given three times daily to a child a year old, and the dose increased in proportion as the age is greater. The disease is undoubtedly in some cases favorably modified by this preparation, as shown by diminution of the violence of the paroxysms, and of the frequency of their recurrence; these effects of remedies can generally be appreciated when the affection has not already continued sufficiently long to attribute the improvement to a spontaneous decline. It is not easy to appreciate the fact of the duration being abridged, as the natural duration varies within wide limits. This remedy probably acts upon the bronchitis. Meigs considers the cochineal as inert, and states that he has found the same benefit from the carbonate of potassa alone, dissolved in syrup of gum and water.[1]

Alum, which was recommended highly by Golding Bird, is considered by Meigs as giving more decided and satisfactory results than any other remedy which he has employed. From one to six grains may be given every four hours, the dose being graduated to the age. Dissolved in some form of syrup and water, it is not an unpleasant remedy. This remedy probably exerts its curative effect by acting upon the bronchitis.

Belladonna has been recommended as a valuable curative remedy by many physicians in different countries. Trousseau lays down certain rules with regard to its administration, which he deems essential in order to secure its curative efficacy. The dose at first should be quite small—one-tenth of a grain of the extract for a child a year old, and one-fifth of a grain for a patient four years, or more, of age. The quantity to be taken in the twenty-four hours is to be given in a single dose. The dose is to be gradually increased until its effect upon the severity or frequency of the paroxysms is apparent. It should then be continued steadily without further increase. The action of this remedy is doubtless upon the neuropathic element of the affection. Some have regarded conium, stramonium, and hyoscyamus as not inferior to belladonna in this affection. The leaves of the chestnut tree (Castanea) have long had a popular reputation, and many physicians have confidence in their curative effect. The infusion is the form generally used, an ounce of the leaves to a pint of boiling water, and given freely.

Strong testimony has been borne by not a few physicians to the curative efficacy of nitric acid. To a tumblerful of well-sweetened water the acid is to be added until the acidity is of the strength of pure lemon-juice; of this a dessert-spoonful is to be given to a child a year old every hour, and a larger quantity above that age.

Since the bromides were introduced into medical practice, they have been employed considerably in this affection, and with apparent benefit. These remedies are probably useful as pharyngeal and laryngeal anæsthetics; hence they are addressed to the neuropathic element of the affection.

Other remedies which have been recommended, and which I shall simply name, are tannic acid, assafœtida, arsenic, quinia, chloroform, the oxide of zinc, and ergot. A method of treatment, which it was claimed had proved remarkably successful, was some years since brought before the French Academy of Medicine, namely, inhalation of the fumes disengaged in the purification of coal-gas. It having been observed that children living in the vicinity of gas works suffered but little from whooping-cough, and recovered

[1] A Practical Treatise on Diseases of Children. By J. Forsyth Meigs, M.D.

after a short career of the affection, the effect was tried upon a large scale, and, as stated by Commerege and Bertholles, in their reports to the French Academy, with signal benefit to a large proportion. To secure the advantage of this measure, patients should inhale the fumes at the place where the gas is purified, for the space of two hours at a time, for twelve consecutive days.[1] It would appear from the statements by Blache, Barthez, and Roger that this measure is often inefficacious. It is, however, sometimes promptly curative.

Of the different remedies which have been noticed, all are doubtless more or less curative in a certain proportion of cases. It may be doubted if any of them ever have a specific effect. They are, severally, useful in some, and not in other, cases; the degree of the usefulness of each varies in different cases, and, with our present knowledge, the physician cannot judge beforehand what particular remedy in any individual case will be most useful. Under these circumstances, if those first selected prove inefficacious, others are to be successively tried.

Palliative treatment is important. Relief may be afforded by opiates in small doses, if they be well borne, by ethers and the hydrocyanic acid. The latter remedy is, of course, to be given with great caution. Strong coffee has been found to be sometimes useful as a palliative. The hydrate of chloral has been found to be an effective palliative remedy; but the physician is not justified in incurring risk of the occasional danger attending its use, even in small doses, especially when the patient is a child, and the object is simply palliation. Many of the anti-spasmodic remedies are useful as palliatives; of these, the value of musk in this, as in other diseases, is perhaps not sufficiently recognized in this country.

Prof. J. Lewis Smith has found the inhalation of carbolic acid spray decidedly useful in diminishing the frequency and the severity of the paroxysms of cough. Spray from the following mixture was inhaled from the steam atomizer, three times daily, from two to five minutes: Acid. carbolic. ʒss, potass. chlorat. ʒij, glycerinæ ʒij, aquæ ʒvj.[2] Prof. Smith calls attention to the apparent effect of the treatment which of late years has consisted chiefly of palliative and sustaining measures, upon the mortality from this disease. Fifty years ago, in the city of New York, the proportion of deaths attributed to whooping-cough, to the deaths from all diseases, was 1 in 76, whereas, at the present time, it is less fatal than any other severe contagious malady.

Hygienic measures form an important part of the treatment. If there be no complications which interfere with exposure to the open air, this should by all means be advised and enforced. Under proper prudential restrictions, the more out-of-door life the better. The diet should be nutritious. If, from the frequency of vomiting, the system suffer from innutrition, alimentation becomes an important object of treatment. The patient should take food often, and as soon after a paroxysm as possible. The times chosen for giving food should be as remote from an expected paroxysm as practicable, and eating at the most favorable times should be insisted upon despite the absence of appetite. Solid is to be preferred to liquid food, as less likely to be rejected by vomiting. Trousseau states that in some cases patients vomit with the paroxysms which occur in the daytime, and not with those occurring during the night; and in such cases food should be taken freely during the night. The stomach is sometimes made to tolerate food by minute doses of opium. Change of air is sometimes of signal efficacy in modifying the severity of the affection and bringing it to a close.

Hemorrhages, if profuse or recurring frequently, claim hæmostatic measures of treatment.

Complications call for the therapeutical measures appropriate under other circumstances, making due allowance for the effects of this affection on the circulation, the blood, nutrition, and the general strength of the system.

There is no known method of preventing the disease, other than by isolation as regards exposure to the contagium.

CHAPTER XI.

PULMONARY HEMORRHAGE. PULMONARY GANGRENE. PULMONARY ŒDEMA. CARCINOMA. HYDATIDS.

Pulmonary Hemorrhage. Bronchorrhagia. Pneumorrhagia. Pulmonary Gangrene. Pulmonary Œdema. Carcinoma within the Chest. Hydatids.

PULMONARY hemorrhage may have as its source, *first*, the bronchial mucous membrane, and, *second*, the parenchyma of the lungs. When from the former source, it is called *bronchorrhagia*, and from the second, *pneumorrhagia*. The source of the hemorrhage also may be exterior to the lungs. The most frequent example of this is the rupture of an aneurismal tumor into a bronchus. Hemorrhage having its source in the pulmonary parenchyma may attend diseases in which the air-cells remain intact, and diseases causing destruction of the pulmonary parenchyma, especially pulmonary tuberculosis and pulmonary gangrene.

Bronchorrhagia exists in the majority of the cases in which hæmoptysis occurs. The latter term should be limited to the spitting of blood, and should be applied only to the cases in which pure or unmixed blood is expectorated. It is not properly applicable to sputa streaked with blood in cases of bronchitis, nor to blood intimately mixed with mucus and inflammatory products in the rusty expectoration of pneumonitis. A true hæmoptysis is the raising of blood, and blood only. In bronchorrhagia the seat of the hemorrhage is most frequently in the small and terminal bronchi. Hemorrhage from the larynx, trachea, or large bronchi is infrequent. In the rare cases in which the loss of blood has occasioned death, it has not been found possible to demonstrate the source of the hemorrhage. The blood probably comes from rupture of capillaries and other minute vessels in the mucous membrane of the small bronchi.

It is important to determine, when blood is ejected from the mouth, whether it comes from the air-passages. It may come from the stomach, from the posterior nares, and from the mouth or fauces. If it come from the stomach, it is ejected by acts of vomiting; it is likely to be commingled with other contents of the stomach; it has the characteristic acid odor of the latter, and it gives an acid reaction, whereas pure blood is alkaline. Coming from the stomach, it usually has a black grumous appearance due to the action of the gastric acids. In some cases of profuse bronchorrhagia, considerable blood may be swallowed and afterward vomited. In a case which I saw in an emergency, the blood coming most profusely from the mouth and nose, the source of the hemorrhage was evidently within the air-passages. Some hours afterward, when the patient was seen by the attending physician, the hæmoptysis had ceased, and a considerable quantity of blood was exhib-

ited which had evidently been vomited. In this case there was both hæmoptysis and hæmatemesis, the latter following the ingestion of blood derived from the air-passages. On the other hand, blood which has flowed into the stomach from the erosion of a large vessel, and is vomited before it becomes mingled with the gastric juice, may retain a bright red color and its alkalinity. If it come from the posterior nares, it is in the form of dark solid sputa which are removed by acts of hawking. If it come from the mouth or fauces, the fact may generally be ascertained by a close inspection of these parts. When it comes from the air-passages, it is raised by acts of coughing, which are generally not violent; the blood rises into the trachea and larynx, and is expelled with slight efforts. In the majority of cases, the blood is liquid, of a bright arterial hue, and contains air-bubbles in more or less abundance. If, however, the hemorrhage have taken place slowly into the bronchial tubes and remained there for some time before being expectorated, it undergoes coagulation and acquires a dark or almost black appearance.

The amount of hæmoptysis varies much in different cases. It is sometimes quite small, a drachm or so of blood only being raised; usually, however, when the amount is relatively small or moderate, several drachms or a few ounces are expectorated. Not infrequently the amount is considerable. It is not rare for patients to lose, during an attack of hæmoptysis, from half a pint to a pint of blood, and sometimes a much larger quantity. The blood is expectorated with more or less rapidity. The continuous duration of an attack of hæmoptysis may vary from a few minutes to several hours and even many days; in the latter case, of course, the blood escaping slowly. Occasionally the flow of blood is so rapid that it escapes simultaneously from the nose and mouth; and death by suffocation may result from the accumulation in the air-passages. A single attack only may occur, or attacks may be repeated at intervals varying greatly in duration in different cases. In some cases attacks recur daily, or repeatedly during the day, for a variable period. In other cases the attacks recur after days, weeks, months, or years. After an attack it is common for the expectoration to be more or less colored with hæmatin for several days. In proportion as it is rapidly discharged it is less frothy than when the quantity expectorated with each act of coughing is small. When the hæmoptysis is rapid and abundant, if the patient be not in advanced phthisis, the bursting of an aneurism should be suspected. The hemorrhage from this source, however, is not always at first abundant and rapid, the opening being, for a time, too small for the free escape of blood. In cases of phthisis advanced to the cavernous stage, the hæmoptysis may be rapid and abundant, leading sometimes to fatal syncope, the hemorrhage being due to the opening of a vessel contained in one of the bands of pulmonary tissue which frequently traverse tuberculous cavities, or to the rupture of the minute aneurismal dilatations which late observations have disclosed in the walls of these cavities.

In the majority of cases, bronchial hemorrhage is, in some way, pathologically connected with pulmonary phthisis, and, from the frequency of this connection, it is important as a diagnostic symptom of that disease. Not infrequently it is the first event which awakens the attention of patients to the existence of pulmonary disease. In a large proportion of cases it occurs more or less frequently during the progress of phthisis. In a certain proportion of cases it precedes that disease; or, at all events, it occurs when physical signs do not afford evidence of its existence, these signs becoming developed, sooner or later, after its occurrence. Rindfleisch believes that when hæmoptysis is followed by symptoms of phthisis, tubercles already exist in the walls of the terminal bronchi, and that the hemorrhage is the result of a tuberculous infiltration of the terminal branches of the pulmonary artery.

Hæmoptysis should always excite a strong suspicion of either existing or impending tuberculous disease; yet, its significance in this respect was undoubtedly over-estimated by Louis in his treatise on phthisis. Louis, having questioned a large number of patients affected with various diseases other than tuberculosis, and finding that spitting of blood had taken place in no instance save after injury of the chest or when the catamenia were suppressed, concluded that this symptom is almost pathognomonic of phthisis. Since the publication of that work, however, it has been found that cases are not very infrequent in which hæmoptysis is not accompanied nor followed by either the symptoms or signs of tuberculous disease. A paper communicated by the late Prof. John Ware contains statistical information of special value with reference to this point.[1] Ware, in this paper, gave the results of an analysis of 386 cases of hæmoptysis, noted in private practice during a period of about forty years. Of these cases, in 62 recovery from the bronchial hemorrhage took place, and the patients afterward were either known to be living in ordinary health, or to have died of other diseases having no connection with the existence of tubercles. The length of time during which this immunity continued varied from two to thirty-seven years. In addition to these cases, in 52 a similar complete recovery took place, and, so far as known, there was no development of tuberculous disease, but the entire subsequent history of these cases had not been obtained. Making allowance for the probable occurrence of a small phthisical affection which underwent arrest and did not return, in a certain proportion of the cases, these facts show that neither the existence of phthisis nor a strong proclivity thereto is to be positively predicated on the occurrence of bronchorrhagia. They show, moreover, that, as regards any immediate or remote evils, bronchial hemorrhage may be innocuous. These conclusions are corroborated by the facts developed by my own clinical studies relating to phthisis.[2]

Bronchorrhagia is incidental to certain cardiac lesions, especially those involving obstruction at the mitral orifice. These lesions lead to bronchial hemorrhage by inducing pulmonary congestion. It may occur in connection with morbid conditions of the blood and tissues, which lead to hemorrhages from the mucous membrane in different situations, as in purpura hemorrhagica and scorbutus. It occurs occasionally in asthma. It may be produced by violent and prolonged muscular exertions, without the co-existence of any pulmonary or cardiac affection, and it has been observed to occur from muscular exertions, not excessive, if conjoined with diminished pressure of the atmosphere in elevated situations, as in ascending high mountains. It may be produced traumatically by injuries and wounds of the chest. It may occur as a secondary hemorrhage when the menses are suppressed. Well authenticated cases of this kind have been reported, but they are exceedingly rare. I have met with a striking example, the hæmoptysis occurring regularly for the four years following the suspension of the menses, and no other pulmonary affection either accompanying or following the hemorrhage. The 386 cases analyzed by Ware did not include a single case in which the hemorrhage could be considered as compensatory for the menses. Exertion and mental excitement, by their effect on the circulation, may act as exciting causes, if, from pulmonary disease or other circumstances, a predisposition exists; but clinical observation shows that, in the larger proportion of cases, the hemorrhage takes place without any apparent exciting cause. It takes place frequently during the night-time.

[1] On Hæmoptysis as a Symptom, by John Ware, M.D., etc. Publications of the Massachusetts Medical Society, 1860.

[2] *Vide* work on Phthisis, 1876.

The occurrence of hæmoptysis generally occasions much alarm and anxiety. If patients be seen at the time, the nervous agitation and disturbance of the circulation, which are often present, are attributable, in a great measure, if not altogether, to the mental condition induced by the attack. The first duty of the physician is to endeavor to remove from the mind of the patient needless apprehensions. Hæmoptysis, proceeding from bronchial hemorrhage, may destroy life either by suffocation or by exhaustion from the loss of blood; but the cases are so rare that the danger of fatal consequences is scarcely to be considered. The physician may assure the patient of the absence of any immediate danger. Nor, in general, does the hemorrhage lead to any evil results. It is suggestive of the existence of phthisis, but, aside from its symptomatic significance, it affords little occasion for alarm. So far from favoring a tendency to tuberculous disease, there is ground for the conjecture that it is sometimes preventive of that disease. And when it occurs in connection therewith, clinical observation shows that it exerts no unfavorable influence on the progress of the disease, but, on the contrary, its influence seems, as a rule, to be favorable.

In exceptional cases, bronchial hemorrhage apparently leads to either the development or an increase of pulmonary symptoms, together with more or less fever; and the immediate local and constitutional sequences are sometimes exceedingly grave. In a case which came under my observation, a young man, apparently in good health, was seized with hæmoptysis while making an evening visit at the house of a friend. The hemorrhage was profuse, and it was not considered prudent for him to return home. When I saw him, a few days afterward, he had a very frequent pulse, great frequency of respirations with dyspnœa, a high temperature, and extreme prostration. Death took place within a fortnight from the date of the attack. I have met with several cases in which, dating from an hæmoptysis, the same symptoms occurred in a lesser degree, the cases ending fatally after a certain number of weeks or months. Such cases, however, are rare. Niemeyer held the opinion that the retention of blood in the bronchi and air-cells after an hæmoptysis excites inflammatory changes which lead to cheesy degeneration and phthisis. He considered phthisis to be the result, and not the cause, of this initial hæmoptysis. Experiments, however, have shown that the presence of blood in the bronchi and air-cells may excite a lobular, but never a caseous pneumonia or tuberculosis. The view of Rindfleisch, therefore, is more probable, that the hemorrhage may hasten the development of phthisical symptoms by occluding the bronchi and causing atelectasis and lobular pneumonia, but that, in these cases, tubercles are already formed before the hæmoptysis, and stand in a causative relation to it. In cases of death directly following a profuse hemorrhage, the bronchial tubes have been found, post mortem, filled with clots; and the obstruction of respiration caused by these, doubtless, was the immediate cause of death. Blood-casts of the bronchial tubes are sometimes expectorated.

The measures of treatment directed to the hæmoptysis must have reference to the profuseness, or otherwise, of the hemorrhage and the associated symptoms. Venesection, heretofore, has been frequently employed. This, however, is indicated only in cases in which the patient is full blooded, or the pulse abnormally strong, and such cases are comparatively few. Even in these cases, unless the escape of blood be unusually rapid and abundant, a saline purgative and sedative remedies are to be preferred to bloodletting. If the hemorrhage be profuse and persisting, cold may be applied to the chest, as in hemorrhages in other situations. This may be done by means of compresses wet with iced water, or with ether which refrigerates by its rapid evaporation. The application of the ice-bag to the chest has been recom-

mended, and I have resorted to it with apparent success, and without any untoward consequences. Revulsive measures may be employed, consisting of stimulating pediluvia, sinapisms, and dry cupping. To diminish the amount of blood returned to the heart, temporary ligation of the extremities may be resorted to. I have witnessed a prompt arrest of the hemorrhage by this measure. A popular remedy is common salt which usually has been freely given before patients come under the care of the practitioner. Its efficacy is doubtful, but its use serves to occupy the attention of the patient and friends until medical advice is obtained.

In all cases, quietude of body is to be enjoined, the use of the voice is to be restrained, the apartment should be kept cool, the head and shoulders should be raised, the diet should be bland or unstimulating, drinks should be cold, and small pieces of ice may frequently be taken into the mouth. These measures are, doubtless, of more or less importance, yet I have repeatedly known patients who, having become accustomed to attacks of hæmoptysis, paid little or no attention to it, and kept about their ordinary pursuits, as usual, without apparently increasing or protracting the hemorrhage by this course. I have known a lecturer continue the daily use of the voice in public speaking, without any apparent injury. The measures just enumerated are apt to be continued too long, patients being anxious to prevent a recurrence of the hemorrhage after it has ceased. They may be assured that moderate exercise out of doors, a nutritious diet, etc., will not be likely to reproduce an attack.

Cough, if present, should be quieted by some form of anodyne. Anodyne remedies are also generally indicated by the excited condition of the nervous system. If the hemorrhage be slight or moderate, as a rule, nothing is required in addition to these remedies and such hygienic regulations as may be deemed prudent. If, however, the hemorrhage be considerable and prolonged, hæmostatic remedies are to be employed. Of these, probably ergot is the most efficient. From one to two drachms of the fluid extract may be given hourly or half hourly, according to the urgency of the indication, the doses being repeated for several hours, if required. Krameria, and tannic or gallic acid, are also efficient vegetable astringent remedies. Of the astringents belonging to the mineral kingdom, the acetate of lead has long been considered valuable in this application. The most efficient preparations of this class, however, are the persulphate and pernitrate of iron. The inhalation of astringent remedies in the form of atomized liquids or spray, has been found effective for the arrest of hemorrhage. For this purpose solutions of alum, tannin, and the perchloride of iron may be employed.

I have met with a few cases of persistent bronchial hemorrhage which claim a separate notice. The hemorrhage in these cases was slight, but it continued for a long period, and without other evidence of pulmonary disease. It was not referable to disease of the heart, to suppression of the menses, or to any appreciable cause. Moreover, the hemorrhage was confined to the bronchial mucous membrane; and the blood did not come from either the mouth, throat, or nasal passages. The hemorrhagic expectoration was not pure blood, but a thin, bloody liquid. I have notes of three cases. In two of these cases, after expectorating almost daily more or less of a sero-sanguinolent liquid during several months, recovery took place under the use of tonics and invigorating hygienic measures. In the third case, the hemorrhagic expectoration continued for six years, during which period the patient, a young woman, from time to time came under my observation. Repeated examinations of the chest by others, as well as myself, failed to discover any positive signs of pulmonary disease. During the greater part of the long period just named, there was daily more or less expectoration of liquid containing hæmatin, the quantity being always small. Associated with this symptom were anæmia

and hysterical ailments. Aside from these, nothing was discoverable. The subsequent history of this case is unknown.

Pneumorrhagia, or the extravasation of blood into the air-cells and frequently also into the interstitial tissue, is commonly known as pulmonary apoplexy. There would be no impropriety in this use of the term apoplexy, if we adopted the custom of French writers of expressing by it extravasation of blood in any situation; but with us, when applied to a cerebral affection, it includes cases in which there is no extravasation of blood, and it is not customary to apply it to extravasation elsewhere than in the brain, spinal cord, and lungs. The name pneumorrhagia is to be preferred.

Extravasation of blood into the pulmonary parenchyma may occur either with or without laceration of the pulmonary tissue. Extravasation with destruction of pulmonary parenchyma is called *diffuse* pulmonary apoplexy or *diffuse* pneumorrhagia. In *circumscribed* pneumorrhagia or hemorrhagic infarction, the blood is in the air-cells and interstitial tissue, but there is no rupture of the lung tissue. Hemorrhage with laceration of the pulmonary tissue is most frequently the result, either of traumatism, such as stab-wounds and gunshot injuries of the lungs, or of the rupture of an aneurism adherent to the surface of the lungs. The blood lies in a cavity, of which the walls consist of torn lung-tissue. The tissue surrounding the cavity is usually diffusely infiltrated with blood. There may be at the same time rupture of the pleura followed by a discharge of blood into the pleural sac. This diffuse hemorrhage, with destruction of the pulmonary parenchyma, is less frequent, but more serious, than the circumscribed form.

In cases of bronchial hemorrhage, the blood may be drawn by inspiration into the air-cells, and produce the appearance of hemorrhagic infarction. Blood may be inspired likewise into the air-cells in cases of wounds of the lingual artery, or of suicide by cutting the throat. Hemorrhage from phthisical cavities and from gangrenous disintegration of the lungs is noticed when treating of these affections. Excluding these conditions, the most important causes of pneumorrhagia without laceration of pulmonary tissue are, active and passive congestion of the lungs, injuries and disease of the central nervous system, especially cerebral hemorrhage, diseases attended by a hemorrhagic diathesis, as scorbutus, purpura, yellow fever, and acute yellow atrophy of the liver, and either thrombosis or embolism of branches of the pulmonary artery.

The term *hemorrhagic infarction* is applied especially to hemorrhage following embolism of branches of the pulmonary artery, the most frequent and important of the causes just mentioned. These embolic infarctions are firm, dark red in color, and wedge-shaped, with the base of the wedge toward the surface of the lung and the apex toward the hilum. In the majority of cases the base of the infarction reaches the surface of the lung, the pleura over the infarction being usually coated with a delicate layer of fibrin. These infarctions may be single, but they are frequently multiple. They may occupy the greater portion of a lobe, but usually they are about the size of a walnut or pigeon's egg. They are most common in the posterior portion of the lower lobe. The affected portion of lung is airless. The microscopical examination shows the air-cells filled with blood, and the alveolar septa compressed and infiltrated with red blood-corpuscles. There are fewer nuclei than normal in the walls of the alveoli, in consequence of coagulation-necrosis (page 53). The tissue surrounding the infarction is congested, œdematous, or solidified with pneumonic products. Emboli may lodge in branches of the pulmonary artery without causing hemorrhagic infarctions. Although the branches of the pulmonary artery do not anastomose with each other, and therefore belong anatomically

to the terminal arterial system, blood may be brought to the capillaries of an occluded artery by means of anastomoses with the bronchial artery and other small arteries which enter the lung (Küttner); and by means of surrounding capillaries. In many cases these anastomoses suffice to carry on the circulation in a district, the main artery of which has been obstructed by an embolus. But if the circulation be enfeebled by weakness of the right side of the heart, or, if there be obstruction to the flow of blood from the pulmonary veins into the left side of the heart, the anastomoses no longer are sufficient, and a hemorrhagic infarction results within the district, the artery of which contains an embolus. Cohnheim's explanation has been generally accepted, according to which the blood in the infarction is derived by a regurgitant flow from the veins leading from the affected district; but, according to Litten's recent experiments, the blood is brought to the capillaries of the occluded artery by the small anastomosing arteries mentioned, the pressure in which does not suffice to force the blood into the veins. The blood escapes by diapedesis and not by rhexis. (See Embolism and Thrombosis, Part I. p. 31.) Infarctions are more frequent in the periphery than in the interior of the lungs, because the anastomoses are fewer and the circulation feebler in the former situation. If life be prolonged, the blood in a hemorrhagic infarction may be in great part absorbed, and only pigmented fibrous tissue, or, possibly, only a pigmented stain, be left behind.

In the majority of cases, hemorrhagic infarctions in the lungs are associated with cardiac disease, especially with mitral obstruction or regurgitation. They appear when the right cavities of the heart have become weakened and dilated, and thrombi have formed in the right auricle or ventricle. These thrombi are the source of emboli which are carried into branches of the pulmonary artery. It is possible that thrombi may form in branches of the pulmonary artery in heart disease. Pulmonary infarctions may be the result also of emboli derived from thrombi in the peripheral veins, as in cases of thrombosis of the femoral vein. It is not always possible to demonstrate a source of emboli in cases of pulmonary infarction.

The diagnosis of either form of pneumorrhagia is, by no means, always easy. Hæmoptysis is, of course, present when the source of the hemorrhage is bronchial, and the extravasation is due to the inhalation of blood into the cells. This symptom is also present in the majority of cases in which the hemorrhage takes place within the cells, but it may be wanting. When present, the hæmoptysis may be either small or abundant; the amount of extravasation is by no means in proportion to the quantity of blood expectorated. The respirations are hurried and labored in proportion to the extent of lung solidified by the extravasated blood. Dyspnœa and a sense of oppression are also proportionate to the degree in which the respiratory function is compromised. These symptoms, however, are measurably due to the co-existing cardiac lesions when the latter stand in a causative relation to the hemorrhage. Dulness on percussion will be found over a space, or over spaces, corresponding to the situation and extent of solidification. This may not be appreciable if the extravasion be in the form of small disseminated nodules. But if the extravasation be diffused over a considerable space, the dulness becomes a very significant sign, provided tuberculosis, pneumonitis, and other affections involving solidification can be excluded. A feeble bronchial respiration may be associated with the dulness on percussion, or the respiratory sound may be suppressed over the extravasation. The presence of blood in the cells and smaller air-tubes will be likely to give rise to the subcrepitant and perhaps to a well-marked crepitant râle within a limited space. These signs, suddenly developed in connection with hæmoptysis, and with mitral

cardiac lesions, may lead to a diagnosis; but in the cases in which no blood is expectorated, a positive diagnosis is extremely difficult if not impracticable.

Circumscribed extravasation, incidental to bronchial hemorrhage, is not necessarily serious; and perhaps it occurs, to a limited extent, not infrequently in cases of abundant hæmoptysis followed by recovery. If there be no injury of the pulmonary structures, and the blood simply infiltrate the air-cells, it may be gradually removed by absorption and expectoration, the normal condition being restored, as after solidification from pneumonitis. If due to embolism, the hemorrhage may lead to gangrene; or the infarcted portions may become the sites of embolic pneumonia and the so-called metastatic abscesses. The latter do not occur unless the emboli contain infectious matter. If these results do not follow, and the number and size of the spaces in which the extravasation has taken place be not large, recovery may take place. When, however, the hemorrhage into the air-cells and into the areolar tissue is considerably diffused, the termination is usually fatal, and death may take place speedily. Other things being equal, the gravity of the symptoms and the immediate danger are in proportion to the amount of extravasation.

The treatment of different forms of pneumorrhagia must have reference to the symptomatic indications in particular cases, in addition to analeptic and supporting measures.

Pulmonary Gangrene.

Pulmonary gangrene may be defined as death or necrosis of lung tissue, accompanied by decomposition. It is one of the infrequent pulmonary affections. Its occurrence in cases of lobar pneumonitis and of hemorrhagic infarction has already been referred to. Its most frequent causes are those which either lower the vitality of portions of the pulmonary tissue, or favor the introduction into the lungs of decomposing or infectious substances. Among the causes may be mentioned, interruption of the blood current, by compression or embolism, in the pulmonary or bronchial vessels, infectious diseases, especially those accompanied by the formation of septic emboli, penetrating wounds of the lungs, severe contusions of the chest, decomposition of the contents of bronchiectatic and of tuberculous cavities, the entrance of foreign substances into the bronchi, such as bits of food in attempts to feed, artificially, insane patients, the ulceration of abscesses and of tumors (*e. g.* cancer of the œsophagus) into the bronchi, etc. Pulmonary gangrene occurs more frequently in males than in females, and in those whose powers of resistance are enfeebled by alcohol, poverty, bad hygiene, or disease. It sometimes occurs as an idiopathic affection in previously healthy individuals, without any apparent cause.

It is presented in two forms, distinguished as *diffused* and *circumscribed*. In the circumscribed form the gangrene occurs in sharply defined spots of variable size, usually between that of a bean and that of a hen's egg. There may be only one gangrenous focus or there may be several foci. They are more frequently situated in the periphery than in the central parts of the lung, and more frequently in the lower than in the upper lobes. The gangrenous spot at first is dark brown or greenish, dry and friable. Later it undergoes softening, and a cavity is formed with sloughy walls, containing an extremely offensive greenish or brown fluid holding in suspension shreds of decomposed lung-tissue. The microscopical appearances of the fetid contents of the gangrenous cavities are identical with those of the sputa. The lung-parenchyma immediately surrounding the gangrenous centre is usually in the

condition of lobular pneumonia; not infrequently it is the seat of hemorrhages. The gangrenous process tends to spread peripherally. In the cases in which the disease terminates in recovery, the walls of the cavity become cleaned off and free from the adherent shreds of lung-tissue; a kind of pyogenic membrane is formed, and, finally, by adherence between the opposite sides of the cavity, or by the growth of granulations, the cavity is entirely obliterated, a cicatrix only remaining. In the process of extension of the gangrenous process, the bloodvessels are usually thrombosed before they disappear; but sometimes they are opened before they become impervious to the blood current, and then severe and even fatal hemorrhage may ensue. When the gangrenous patch reaches the surface of the lung, the overlying pleura is covered with a layer of fibrin; frequently general pleuritis results, which may be of a gangrenous character. Sometimes the gangrenous focus opens into the pleural cavity, giving rise to pneumo-pyothorax. Thrombi may form in the veins in the neighborhood of the sloughy centres in the lung. From this source infectious emboli may be carried to the various organs of the body. Intense bronchitis, sometimes of a diphtheritic character, may result from the irritation of the gangrenous material.

Diffuse gangrene may be secondary to the circumscribed form, or it may be diffuse from the first. The greater portion of a lobe, a whole lobe, or even a whole lung, may be involved. The pulmonary parenchyma is broken down into a putrid, greenish, or blackish pulpy mass, without evident line of demarcation. It is always fatal.

The symptoms in cases of gangrene relate measurably to the general condition or to associated affections. The pulmonary symptoms due to the gangrenous condition, at first, are those which belong to circumscribed pneumonitis, consisting of cough, some pain, and accelerated breathing, and, after a time, an expectoration, more or less abundant, of characteristic appearance and odor. The gross and the microscopical appearances of the sputa have been studied carefully by Traube[1] and by Leyden and Jaffé.[2] The sputa are of a yellowish, greenish, or brownish color, according to the varying amount of pus and of blood present. They emit a penetrating, intensely fetid odor. When fresh they are alkaline, but upon standing become acid. By allowing the expectoration to stand for a while in a glass dish, three distinct layers become visible; the upper is frothy, opaque, and of a dirty gray or yellowish color, the middle is clear and watery, the lower is greenish and purulent, or it may be brownish from admixture with pigment or blood. In this lower layer are shreds of lung tissue visible to the naked eye, and gray or whitish masses. Microscopical examination reveals granular detritus, pus corpuscles, triple phosphate crystals, drops of fat, and acicular crystals of the fatty acids often in bunches. In addition, granular or angular fragments of brown or black pigment, numerous round and rod-shaped bacteria, also spiral bacteria, leptothrix threads, and infusoria are met with. The bacteria and fatty drops and crystals are often compacted together into little yellowish clumps visible with the naked eye. The shreds of lung-tissue seen with the naked eye are of a dirty gray or black color, and consist chiefly of granular detritus, dark pigment and bacteria with occasionally some elastic fibres. Elastic fibres are rarely present, according to Traube, in the gangrenous expectoration. Later observations seem to show that Traube underestimated the frequency with which elastic fibres are found in gangrenous sputa; still, it remains true that the microscopical shreds of lung tissue frequently found in the expectoration of pulmonary abscess contain numerous elastic fibres, often marking out the out-

[1] Deutsche Klinik, 1853, 1859, 1861, *et seq.*
[2] Deutsches Archiv f. klin. Med., ii. p. 488.

lines of the alveoli, whereas elastic fibres are more scanty in the shreds of tissue in the sputum of pulmonary gangrene.[1]

Pulmonary gangrene may be confounded with fetid bronchitis, decomposition in the contents of dilated bronchi and of tuberculous cavities, and with pulmonary abscess. The diagnosis is not to be based upon the gangrenous odor of the breath and sputum alone. In fetid bronchitis and in cases of decomposition of the contents of pulmonary cavities, macroscopical shreds of lung-tissue are not present in the expectoration; in pulmonary abscess they are often present, but they contain abundant elastic fibres which are less numerous and often absent in pulmonary gangrene. Again, pulmonary abscess is not usually accompanied by the fetor of gangrene.

In cases of circumscribed gangrene, the gangrenous portion of lung, together with the solidification from inflammatory exudation around this portion, furnishes dulness or flatness on percussion within a circumscribed space which, in view of the most frequent situation of gangrene, will generally be over the scapula below the spinous ridge. Within this space either the respiratory murmur is wanting, or there is a feeble bronchial respiration, with, perhaps, either exaggerated vocal resonance or weak bronchophony. Moist bronchial or bubbling râles are likely to be heard within and around this space. If the patient survive the sloughing and removal by expectoration of the decomposed mass, the cavernous signs may be discovered. I have repeatedly found a well-marked cavernous respiration; and I have observed a circumscribed depression in front corresponding to the situation and size of the gangrenous cavity.

As regards prognosis, if circumscribed gangrene do not occur under circumstances which are dangerous, irrespective of the gangrene, recovery may take place. The chances of recovery are differently estimated by different writers, which perhaps may be accounted for by supposing that the diagnosis of gangrene is not infrequently based on insufficient grounds. It can hardly be doubted that the result is fatal in a large majority of cases. Hæmoptysis, as already stated, sometimes take place in connection with the separation of the slough, and I have known the hemorrhage to be so abundant as to prove the immediate cause of death. Cases in which the gangrene involves the pleura, perforation of the lung taking place, followed by pleuritis with pneumothorax, probably always end fatally.

The treatment of pulmonary gangrene is to be directed more to the system than to the local affection. The affection never occurs under circumstances which render depletion or other debilitating measures appropriate; on the contrary, such measures can hardly fail to be pernicious. Tonic remedies are indicated, and the sustaining treatment. The diet should be as nutritious as possible, and alcoholics are to be given with a freedom proportionate to the tendency to failure of the vital powers. The employment of opium, in some form, is important, in order to palliate pain or undue cough, and to allay constitutional irritation. The chlorate of potassa has been suggested as likely to be useful, from its apparent usefulness in gangrenous affections of the mouth and throat. The tincture of the chloride of iron is suggested by the same analogy. Disinfectants, by inhalation, are indicated as long as the sputa contain decomposed matter, and the breath has a fetid odor. The

[1] According to the experiments of Filehne—Ueber die Vorgänge bei dem Lungenbrande, Sitzungsberichte der phys. med. Soc. zu Erlangen, Jan. 11, 1877—in the sputum of pulmonary gangrene a digestive ferment is present capable of dissolving in alkaline solution the elastic fibres and albuminous substances, but not acting on ordinary white fibrous tissue which may be found in gangrenous sputum when the elastic fibres are absent. Elastic fibres resist putrefactive changes much longer than digestion.

vapor of turpentine poured upon boiling water is a disinfectant, and has otherwise a salutary local effect. Tar vapor, produced in the same way, is useful. A solution of carbolic acid of the strength of from two to four per cent., atomized, and inhaled for a few minutes at short intervals, is probably the best disinfectant. Thymol and salicylic acid are recommended as appropriate for disinfecting inhalations.

Pulmonary Œdema.

Pulmonary œdema is always dependent on other pathological conditions, and is not entitled to be considered as an individual affection. It is, however, an event of frequent occurrence, and is important as interfering with the function of respiration, and, in not a few instances, proving the immediate cause of death. In œdema of the lungs there is a transudation of serum into the interlobular tissue, the alveolar walls and the air-cells.[1]

Œdema may be localized around some diseased centre in the lung, as, for example, in the neighborhood of a pneumonitis, an infarction, abscess, tumor, etc. This is distinguished as *collateral œdema*. It probably results from a moderate inflammatory change in the vessel-walls by which their permeability is increased. It has also been called inflammatory œdema. Hypostatic œdema following hypostatic congestion, and leading to the condition of lung called splenization, has already been referred to.

These forms differ from general pulmonary œdema which is usually understood by the term œdema of the lungs. Here a serous transudation occurs throughout both lungs, except in portions which may, perhaps, present a mechanical obstacle to the entrance of the serum in consequence of consolidation, as from compression, inflammatory exudation, new growths, etc. Œdematous lungs are increased in volume and weight; retract less than healthy lungs upon opening the chest; have a characteristic boggy feel compared to that of a sponge filled with water, and pit on pressure. They are less buoyant than normal lungs, but they do not sink in water. The color is usually red, but it may be pale. On section, a serous or sero-sanguinolent liquid escapes in abundance, usually mixed with numerous air-bubbles. The same frothy liquid is present in the bronchi and usually in the trachea. Microscopical examination, in cases of acute general pulmonary œdema, shows the pulmonary capillaries widely distended with blood, and the contents of the alveoli and bronchi to consist of serum containing a considerable number of red blood-corpuscles, some granulated epithelial cells washed off from the alveolar walls by the transuding serum, and free granular matter. The red blood-corpuscles, which are always present in the serum, have escaped by diapedesis. The serum infiltrates also the alveolar septa.

Œdema of the lungs may occur under various pathological conditions. There is hardly a grave disease, acute or chronic, which it may not complicate. It is also true that there is no disease of which it is a necessary accompaniment. It occurs often during the death-agony, when it seems to be rather an accompaniment than the cause of death. Of the affections, during the course or at the termination of which it most frequently occurs, may be mentioned acute and chronic Bright's disease, valvular lesions of the heart, pneumonitis, fevers, especially those of an asthenic type, cerebral lesions, especially hemorrhage and traumatism, and cachexiæ giving rise to a hydræ-

[1] Posner (Virchow's Archiv, Bd. 79, p. 362, 1880) finds that the dropsical effusion is first into the walls of the air-cells, and that it may be confined to them (interstitial œdema). Usually, however, and in the higher grades of œdema always, the serum escapes also into the air-cells.

mic state of the blood. Its occurrence during these and other diseases is especially when the heart's action becomes enfeebled. It is frequently developed suddenly, and may disappear likewise with considerable rapidity. It may prove quickly fatal by interference with respiration. The great variety of conditions in which it appears, the inconstancy of its development under apparently similar conditions, the rapidity of its onset in many cases, its production during the death agony, are among the considerations which, at first, seem to give to it a pathological position having no analogy to the dropsical accumulations in other organs, and which render difficult the explanation of its production.

That hydræmia, pulmonary congestion by obstruction at the mitral orifice, and general weakness of the heart are only predisposing, not immediate, causes of pulmonary œdema, is evident from the fact that as all these conditions may exist in a high degree without the development of œdema of the lungs. This fact is proved both by clinical observation and by the establishment of these states artificially in animals. There must be added some other factor which acts as the immediate and exciting cause; a factor which is capable of developing under various conditions; one which can appear suddenly and as rapidly disappear. It is also to be assumed that this factor must be something which will increase the blood-pressure in the pulmonary capillaries, for, that œdema of the lungs is a mechanical œdema, that is, a result of increased tension in the capillaries of the lung, is rendered probable by microscopical appearances and by our knowledge in general of dropsical effusions. That mechanical hindrance to the outflow of blood from the pulmonary veins, as by mitral stenosis, is capable of producing this elevated tension seems *à priori* probable; but this is a condition present in only a minority of cases of pulmonary œdema, and the experiments of Welch,[1] in reference to the cause of œdema of the lungs, have shown that the obstacle must be greater, in order to produce œdema, than can well occur in man. He, however, found that an efficient cause of pulmonary œdema existed in paralysis of the left side of the heart, the force of the right side being not at all or less impaired. Neither general paralysis of the heart, nor weakness alone of the right ventricle, sufficed to produce pulmonary œdema. But, as was proved experimentally, it appeared when the left ventricle was so disproportionately weakened that it could not propel into the general circulation the same amount of blood propelled by the right ventricle into the lungs. The blood accumulated in the lungs until the tension in the pulmonary capillaries became sufficient for the transudation of serum through the vascular walls. The assumption that disproportionate paralysis of the left ventricle is the immediate cause of acute general pulmonary œdema in man, would explain many of its singular phenomena. Such a condition of the heart can be readily supposed to develop suddenly, to rapidly disappear, and to arise during manifold diseases, especially when the general activity of the heart is impaired; for it is not denied that the general force of the heart is weakened in most cases of pulmonary œdema, and, indeed, it is hardly conceivable that the left ventricle should lose its wonderful power of adaptation to the obstacles which it has to overcome in propelling the blood, before the whole heart had suffered in its function. Œdema of the lungs occurs during the death agony when the left ventricle loses its power more rapidly than the right, or dies faster, so to speak. While the hypothesis of Welch as to the immediate cause of pulmonary œdema is not controverted by clinical facts, but, on the other hand, seems to explain them better than any other, we as yet know of no means of determining in man the relative force of the two

[1] William H. Welch, Zur Pathologie des Lungenödems, Virchow's Archiv f. path. Anat., Bd. 72, 1878.

sides of the heart, and upon the absolute strength of either right or left ventricle only subordinate weight is placed. Other influences adduced to explain the cause of œdema of the lungs, are impaired nutrition of the walls of the pulmonary capillaries and vaso-motor disturbance.[1]

The symptoms of œdema are increased frequency of the respirations and dyspnœa, in proportion to the extent of lung affected, together with more or less cough and serous expectoration or bronchorrhœa. The displacement of air in the air-cells by liquid, gives rise to dulness more or less marked on percussion over a space corresponding to the œdematous portion of lung, and within this space the respiratory murmur is weak or lost, or it may be feebly bronchial or broncho-vesicular. The vocal resonance may be increased. The presence of liquid in the smaller bronchial tubes is denoted by fine mucous or subcrepitant râles. It is stated that a true crepitant râle may be produced, but this must be extremely rare. The diagnosis is to be based on dulness more or less diffused on both sides of the chest, associated with moist bronchial râles, pneumonitis being excluded, and the existence of Bright's disease, cardiac lesions and other predisposing conditions, being considered.

The treatment must have reference to the circumstances under which the œdema occurs. Occurring in connection with disease of the kidneys, those measures are indicated which are applicable to dropsical effusion in other situations, namely, hydragogue cathartics, and sudorifics, selected and regulated according to the circumstances belonging to individual cases. When incidental to disease of the heart, the main reliance is upon revulsive measures, in connection with such remedies as the condition of the heart may claim irrespective of this result. In the cases in which it is dependent on adynamia and an impaired condition of the blood, tonic and sustaining measures are called for. The liability of its occurrence in connection with hypostatic congestion, in fevers and other protracted diseases, accompanied by feebleness of the circulation and depression of the vital powers, renders it an important part of the treatment of these diseases to see that the patient be not allowed to lie constantly in one position. The position of the body should be frequently changed, in order to obviate the gravitation of blood to the dependent portions of the lungs.

The name *acute* pulmonary œdema distinguishes cases in which the œdema occurs suddenly to such an extent as to give rise to great dyspnœa, and sometimes quickly causing death by apnœa. In such cases, prompt and efficient measures of treatment are called for. Venesection, if the action of the heart be not extremely feeble, is the most promptly efficient measure for relief, and should be resorted to at once when the symptoms denote imminent danger. Perhaps under no other circumstances is it more apparent that the physician has saved the life of a patient than in certain cases of acute pulmonary œdema in which venesection was employed. Occurring in connection with dilatation of the heart, or when accompanied with great feebleness of the pulse and cyanosis, the application of a considerable number of dry cups to the chest may be substituted for blood-letting. To these may be added mustard to the chest and stimulating foot-baths. Ethereal and alcoholic stimulants should be given freely. I have known the inhalation of oxygen to afford marked relief.

New Growths within the Chest.

Intra-thoracic tumors include nearly all the different varieties of new growth with which we are acquainted. Their consideration in detail belongs to works on special pathological anatomy. Reference here will be made only to those rendered practically important by their frequency or gravity. Of this class, carcinoma, sarcoma, and lympho-sarcoma deserve especial mention.

Pulmonary carcinoma is usually secondary to carcinoma in some other situation. It is not infrequently consecutive to cancer of the breast, which may either extend by continuous growth into the pleura and lungs, or give rise to independent cancerous nodules in the latter. In other cases the primary seat of the cancer is in the testicle, uterus, stomach, liver, œsophagus, etc. In so-called general carcinosis, many small cancerous nodules may appear in the various organs and tissues of the body, and the lungs are often thickly studded with the new growth. The secondary deposits in the lungs usually reproduce the structure of the primary tumor. Secondary pulmonary cancer is usually in the form of nodules varying in size from that of a pea to that of an orange and disseminated through both lungs.

Primary pulmonary carcinoma is a very rare affection. In twenty-seven cases analyzed by Reinhard,[1] only one lung was involved in nearly all of the cases—eighteen times the right, nine times the left. The right upper lobe was the most frequent seat. The new growth seemed to spring from the epithelium of the glands or of the mucous membrane of the bronchi. The encephaloid or medullary variety of carcinoma was the one most frequently represented, and generally in the infiltrated form.

In pulmonary carcinoma the bronchial glands and the pleura are usually involved. In some cases the pleura is studded with small cancerous nodules, even when the lungs are but little affected. Hydrothorax is present in these cases, and sometimes pleuritis which is apt to be of a hemorrhagic type. In pulmonary and pleural carcinoma, the new growth extends by preference along the course of the lymphatic vessels, which frequently appear beneath the pleura to the naked eye as if injected with the cancerous elements. According to Cornil and Ranvier,[2] in most cases of pulmonary carcinoma the stroma is represented by the pre-existing alveolar walls and septa, and cancer cells of an epithelial type fill the air-cells. There can be no doubt, however, that in many cases the lung-tissue is replaced by a new growth of stroma as well as of cancer-cells. Sometimes softening and breaking down of the cancerous mass occurs, whence may arise cavities, abscesses or gangrenous foci. Secondary inflammation is present in the lung-parenchyma surrounding the cancerous deposit.

If we accept Waldeyer's view of the structure and of the epithelial origin of carcinoma (page 48), it is probable that many cases which have been recorded as medullary carcinomata, are, in reality, round-celled sarcomata. But as this distinction has at present no clinical bearings, the question will not be here discussed. Spindle-celled sarcoma also occurs in the lungs.

Of the malignant tumors in the lungs, lympho-sarcoma is among the most important. It takes its origin usually in the bronchial or cervical lymphatic glands, and extends, both by continuity and by metastases, into the lung. The structure of the tumor is that of lymphatic tissue, that is, a network of anastomizing fibres or cells densely infiltrated with small round cells called lymphoid cells. Caseous degeneration is rare, but a fibroid metamorphosis is

[1] Der primäre Lungenkrebs. Arch. f. Heilkunde., xix. 3, 369, 1878.
[2] Manuel d'histologie pathologique, p. 715.

more common. The new growth advances chiefly along the adventitia of the bloodvessels and the bronchia.

To the group of intra-thoracic tumors belong also those seated in the mediastinum. They are more frequent in the anterior than in the posterior mediastinum. Lympho-sarcoma, hyperplastic enlargements of the lymphatic glands, hypertrophy and sarcoma of the thymus gland, and secondary carcinoma are among the most important of tumors in this region.

The symptoms of intra-thoracic tumors are both general and local. In suspected carcinoma, the existence of the cancerous cachexia and the presence of carcinomatous tumors in other parts of the body must be considered in arriving at a diagnosis. Lympho-sarcomata present often the history of pseudo-leucocythæmia or adenia of Trousseau. In carcinoma of the lungs, some diagnostic value is to be attributed to enlargement of the supra-clavicular lymphatic glands, and to a muco-hemorrhagic expectoration compared in its appearance to currant jelly. These two symptoms are, however, not pathognomonic nor always present in pulmonary carcinoma. The chest wall on the affected side may bulge; sometimes, however, especially in hard cancer, accompanied by extensive induration, it is contracted.

The diagnosis of new growths within the chest is to be based on the symptoms, taken in connection with the signs of solidification, and sometimes the cavernous signs. The physical evidence is often not very distinctive. Pulmonary phthisis is to be excluded by a careful investigation with reference to the history, as well as the existing symptomatic phenomena. The coexistence of carcinoma in some other situation, or its previous existence, is to be taken into account in arriving at a diagnosis of carcinomatous intra-thoracic disease.

The presence of tumors, great or small, gives rise to dulness or flatness on percussion, with either suppression of the respiratory murmur or the modifications which denote solidification. The tumors may be so situated as to give rise to symptoms and signs proceeding from pressure on important parts other than the lungs. The heart may be displaced. The calibre of the trachea or bronchi may be diminished. Aphonia or laryngeal spasm may be induced, if the recurrent nerve be involved. Congestion limited to the upper extremities, head and neck, and subcutaneous œdema, denote obstruction of the superior vena cava. Pressure on the pulmonary veins may give rise to bronchorrhagia and œdema of the lungs. Compression of the œsophagus occasions difficulty in the ingestion of food and drinks. These results of pressure on adjacent parts also belong to the history of aneurismal tumors. A tumor situated in the tract of the aorta, may simulate the physical signs of aneurism. It may pulsate and give rise to a murmur. I know, from my own observations, that it may occasion a double murmur, that is, a systolic and a diastolic murmur. The enlargement of one lung by a new growth, together with either pleural transudation or suppuration, may lead the physician to suppose that he has to deal simply with a case of pleurisy or empyema. The existence of the underlying graver affection can only be determined after removal of the liquid by aspiration. On the other hand, unilateral contraction of the chest is suggestive of fibroid phthisis.

As regards treatment in carcinoma and other new growths, all that can be hoped for is the prolongation of life by a diet as abundant and nutritious as the digestive powers will allow, together with the best available hygienic influences, and tonic remedies. Palliative treatment is to be employed in accordance with the symptomatic indications.

Hydatids. Echinococci.

Among the extremely rare affections of the pulmonary organs belong hydatid productions. These may either be developed within the lungs, or they have been developed in the liver and have made their way through the diaphragm into the pulmonary organs, in the manner in which hepatic abscesses are sometimes evacuated into the bronchial tubes, circumscribed peritonitis and pleuritis taking place and leading to adhesions which prevent the evacuation from taking place into either the peritoneal or the pleural sac.

Acephalocysts within the lungs may remain for a variable period latent, that is, giving rise to few or no pulmonary symptoms. Sooner or later, however, they excite inflammation of the surrounding parenchyma and bronchial tubes, and then occasion pain, cough, expectoration, febrile movement, etc. They may be discharged by ulceration into the bronchial tubes, leaving pulmonary cavities. The affection is likely to be mistaken for pulmonary tuberculosis. Microscopical examination of the matter expectorated may show the hooklets of echinococci, or pieces of the sac with its characteristic striation and hyaline appearance. Without the demonstration of one of these the diagnosis is impracticable. The question as to the primary seat of the cysts is to be settled by the previous history which, if they come from the liver, will show the existence of hepatic trouble prior to the occurrence of pulmonary symptoms.

The presence of hydatids in the lungs always involves great danger; the danger is greater when they are derived from the liver than when they are developed within the lungs. There is no special plan of treatment. Palliative and sustaining measures are to be adapted to the circumstances of individual cases.

Hypertrophy and Atrophy of the Lungs.

Pulmonary hypertrophy can hardly be said to exist under circumstances rendering it of importance in a practical point of view. Increase of the volume of the lungs from distension or dilatation of the air-cells is not hypertrophy, but, on the contrary, it is associated, in cases of emphysema, with atrophy. True hypertrophy, that is, an actual increase of the tissues forming the pulmonary organs, is stated by Rokitansky and others to take place when owing to abolition of the respiratory function of one lung, the other lung takes on an increased functional activity; the latter becomes hypertrophied. Hypertrophy is also described by Skoda and Virchow as occurring in cases of prolonged pulmonary congestion caused by mitral cardiac lesions or by dilatation of the right ventricle. Under these circumstances, the increase of the pulmonary tissues is at the expense of the capacity of the air-cells; the tissues present a brownish color, and the pigmentary deposits are unusually abundant and large. (*Vide* Brown Induration of Lung, page 185.)

Atrophy of lung is a lesion involved in the form of emphysema distinguished as atrophous or senile, and has been already noticed in that connection.

CHAPTER XII.

DISEASES OF THE LARYNX AND TRACHEA.

Affections of the Larynx and Trachea. Points relating to the Anatomy and Physiology of the Larynx which are involved in the consideration of Diseases in this situation. Acute Simple Laryngitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute Laryngitis. Chronic Laryngitis. Laryngitis with Inflammatory Exudation—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Œdema of the Glottis. Spasm of the Glottis Nervous Aphonia. Paralyses of the Laryngeal Muscles. Morbid Growths within the Larynx.

IMPORTANT diseases affecting the respiratory apparatus are seated in the larynx and trachea. Diseases of the larynx frequently involve the trachea, but it is rare for the latter to be affected without the former, and it will suffice to consider tracheal affections incidentally in treating of those of the larynx.

Certain anatomical and physiological points pertaining to the larynx are to be kept in mind with a view to a clear apprehension of the diseases in this situation. The larynx is composed of a collection of cartilages, namely, the cricoid, thyroid, arytenoid, and epiglottis. The epiglottis was formerly supposed to be essential as a protection against the entrance of food and drink into the laryngeal cavity during the act of deglutition; the removal of this cartilage, however, in inferior animals, has shown that its loss does not occasion serious inconvenience. A hospital case in which it was completely destroyed by syphilitic ulceration, as determined by the touch and the laryngoscope, has fallen under my observation. So long as ulceration existed, there was considerable difficulty arising from spasm of the glottis, excited by contact with food and drink, and deglutition was performed with the least annoyance while the patient was lying on the back. But, after the ulceration had healed, the difficulty nearly ceased, liquids and solids being swallowed without much inconvenience. The quality of the voice underwent some change, and the patient, a young woman, stated that she had not the power of producing notes in singing as before.

The small size of the *rima glottidis* is an important point in connection with laryngeal diseases. In the adult male, after death, it is a triangular space an inch in length, and, at the base, about a quarter of an inch in width, the size being still smaller in women and children. The dimensions in life vary with the two respiratory acts. When examined in a living animal, the vocal cords are found to separate widely in inspiration and to return in expiration, forming the respiratory movements of the glottis. The respiratory movements take place from a reflex influence communicated through the recurrent nerves. These points are of interest and importance in their practical applications.

Other movements of the muscles of the larynx are produced by volition in the acts of speaking. The larynx being the seat of the voice, modifications of vocal sound constitute important symptomatic phenomena of disease. In the movements concerned in phonation, the will acts through branches of the spinal accessory contained in the recurrent laryngeal nerves. The laryngeal muscles are subject to spasm and paralysis.

The solidity of the walls of the larynx is an important point in connection

with certain affections. The cricoid and thyroid cartilages do not readily yield to internal pressure, and hence arises obstruction from the presence of morbid products which encroach upon the small space between the vocal cords. Another point to which reference will be made, is the abundance of areolar tissue beneath the mucous membrane above the vocal cords; this tissue is more abundant in the adult than in the child, a fact which will serve to account for certain differences as regards the effects of disease during and after infantile life.

The mucous membrane of the larynx is covered, for the most part, with ciliated cylindrical epithelium. Over the upper portion of the epiglottis, the true vocal cords and a portion of the posterior surface of the laryngeal cavity, however, the epithelium is of the pavement variety. The mucous membrane is in most places loosely attached by lax connective tissue to the subjacent muscles and cartilage, but over the true vocal cords it is firmly adherent. Hence, in the latter situation submucous inflammatory and serous effusion cannot well occur. Racemose mucous glands are numerous in the larynx. None are present in the true vocal cords. The mucous membrane and the submucous tissue are rich in elastic fibres.

Of the affections of the larynx, those involving inflammation will be first considered. Inflammation here may be simple, that is, not distinguished by any unusual features save those which are incident to the situation of the affected mucous membrane. On the other hand, it may be accompanied by fibrinous exudation. The latter will be considered under a separate head. Simple inflammation may be either acute, subacute, or chronic. These three varieties are to be considered separately. The appropriate name for inflammation affecting the larynx is *laryngitis;* this name should take the place of the terms *angina* and *cynanche*, which were formerly in vogue, but now rarely used. The term *croup* is applied to laryngitis with fibrinous exudation, and it has also been applied to simple laryngitis and to a non-inflammatory affection, namely, spasm of the glottis, occurring in children. The first of these affections is sometimes distinguished as *true croup*, while the others are called, by way of distinction, *false croup*. The term is an unfortunate one, and tends to produce confusion. I shall consider the several affections to which the term has heretofore been applied, separately under their appropriate names.

Acute Simple Laryngitis.

Anatomical Characters.—This variety of laryngeal inflammation is often called acute catarrhal laryngitis. During life the mucous membrane is reddened and swollen, as demonstrated by means of the laryngoscope; but, after death, the congestive hyperæmia is less marked, and may even entirely disappear under the pressure of the abundant elastic fibres. Small ecchymoses are not infrequently observed. The inflammatory products consist of serum and pus mingled with an abundant secretion of mucus. The first product is mostly mucus; later, this becomes opaque from admixture with a larger number of pus-cells, and in severe cases it becomes distinctly purulent. Ciliated epithelial cells do not appear in the expectoration, and they are not usually desquamated. The mucous glands are swollen, and through their orifices, often, little drops of muco-pus can be pressed. The mucous membrane and submucous tissue always contain some pus-cells. The amount of swelling of the loose submucous tissue varies in different cases. In severe cases it becomes so swollen from infiltration with serum and pus as to endanger life by interference with respiration. Sometimes erosions or even superficial ulcerations of the mucous membrane are formed. They either

have their origin from ecchymoses, or they are follicular and seated in the mucous glands.

Clinical History.—The symptoms of acute laryngitis are intelligible when the morbid changes are considered in connection with the small size of the *rima glottidis* and the unyielding walls of the larynx. Simple swelling of the mucous membrane may produce more or less distressing symptoms and danger due to narrowing of the aperture of the glottis. But, with submucous infiltration added, the obstruction is increased, and may prove fatal by suffocation. The obstructive effect of the morbid changes explains the symptomatology and danger. The chief element of danger is the submucous infiltration. This occurs in varying degrees, the severity of the local symptoms and the danger being in proportion to its amount.

The development of the disease may be preceded by subacute laryngitis or a common cold. The voice is at first hoarse, and, with the development of acute inflammation, is lost. The aphonia is accompanied with a stridulous cough and a small expectoration of glairy mucus which may be streaked with blood. Febrile movement is more or less intense or it may be wanting. These symptoms may exist without notable difficulty of breathing, provided the changes are limited to the membrane and the swelling is not great.

With a greater amount of swelling, together with submucous infiltration, labored respiration and dyspnœa are added. The obstruction affects both inspiration and expiration, but more especially the former, owing to the fact that the infiltration is greatest above the rima where the areolar tissue is most abundant. The respiration is stridulous or noisy. The patient complains of a sense of constriction at the larynx, or feels as if the cavity were filled with a foreign substance. The latter symptom may be called *laryngeal tenesmus*. There is frequently more or less difficulty in deglutition. Fluids, by coming into contact with the inflamed epiglottis, excite cough and add to the distress. The labor of breathing and dyspnœa are increased by the occurrence of spasm of the arytenoid muscles. The exacerbations of distress from obstruction are due chiefly to a spasmodic element. Paralysis of the abductor muscles may, in some cases, contribute to the obstruction.

In cases of acute laryngitis with great obstruction, the suffering is intense. The face and eyes are swollen and congested, the countenance denotes anguish, and, after a time, lividity occurs. The distress is much increased during the exacerbations caused by spasm, and in the intervals of comparative ease the patient manifests drowsiness, but is unable to obtain refreshing sleep. With the muscular efforts to enlarge the aperture of the glottis, the larynx rises and falls in the acts of inspiration and expiration. There are frequent efforts to cough and expectorate, as if to get rid of an accumulation within the larynx. The cough may be dry and croup-like, but is oftener husky or abortive. The larynx is sensitive to pressure. Pitting over the *pomum adami* has been observed. The respiratory acts are less frequent than in health. In a case which I have recorded they were twelve per minute.

With these symptoms, in a large proportion of cases the disease ends fatally if tracheotomy be not resorted to. The mode of dying is by apnœa, and it may take place either gradually, or suddenly in an exacerbation of unusual violence.

Assuming that other affections do not co-exist, the symptoms, in addition to those which relate directly to the laryngeal obstruction, are incidental to fever, deficient oxygenation and decarbonization of the blood, together with the suffering which belongs to the disease. Slight delirium may occur toward the close of the disease if it be prolonged, but, in general, the mental faculties are unaffected.

Pathological Character.—In simple acute laryngitis, the inflammation has no special characteristics. The severity and danger are not owing to the intensity or extent of the inflammation. The same amount of inflammation in other situations would constitute a trivial affection. The gravity is due to the fact that the usual results of inflammation in this situation obstruct the passage of air through the larynx, in consequence of the small size of the rima glottidis and the unyielding laryngeal walls. In children, simple acute laryngitis gives rise to croupy cough and respiration, and hence this is one of the different affections formerly embraced under the name croup.

Causation.—Acute laryngitis in the adult is so rare that practitioners of considerable experience may have never met with an example of it. It is less rare in infants and children than after adult age. Its infrequency is remarkable in view of the frequent occurrence of inflammation in the pharynx; and the fact exemplifies the principle of conservatism involved in the law by which inflammation does not tend to extend from one part to other parts, although in immediate proximity. I have seen a case in which the pharynx was laid open by a gunshot wound in the neck, so that the top of the larynx could be seen through the wound, and yet, during the progress of recovery, there was no evidence of the slightest laryngeal inflammation.

Occasionally, however, laryngitis is developed in connection with pharyngitis. This was observed in some cases of the so-called epidemic erysipelas, or "black tongue," which formerly prevailed in many parts of this country. I have known it to occur in connection with the pharyngeal affection in scarlatina. The laryngitis which, in a subacute form, is common in rubeola, sometimes becomes acute. Acute inflammation may be excited in variola by the occurrence of the eruption in this situation. Under the several circumstances just named, it is a secondary affection. It may occur as a primary affection after exposure to cold and wet, as in the case of Washington.

It might be conjectured that excessive use of the voice would be likely to predispose to this affection, but clinical observation furnishes little proof that such is the fact. It may be produced, traumatically, by the inhalation of irritating vapors. A distinguished professor of chemistry, some years ago, lost his life by laryngitis caused by accidentally drawing into the larynx a corrosive acid through a pipette, the extremity of which had been broken. Many cases have been reported in which young children have produced the disease by sucking boiling liquid and steam from the spout of a water- or tea-pot.

Diagnosis.—The diagnostic characters of acute laryngeal inflammation are the loss of voice and the husky, stridulous cough, in connection with the fever and other symptoms. That the labor of breathing and dyspnœa are due to the obstruction of the larynx, is shown by the sensations of the patient, the diminished frequency of the respiratory acts, and the absence of physical signs denoting pulmonary disease. In proportion as the aperture of the glottis is narrowed, the respiratory murmur will be weakened, and this affords a better criterion of the amount of obstruction than the sufferings of the patient. The only difficulties in diagnosis relate to the discrimination of simple acute laryngitis from laryngitis with the exudation of fibrin, from œdema of the glottis, and from spasm of the laryngeal muscles. In arriving at the conclusion that simple acute laryngitis exists, the affections just named are excluded by the absence of distinctive circumstances belonging to the clinical history of each. Suffice it to say here that the presence or absence

of the exudation of fibrin in cases of laryngitis is generally determinable; that œdema of the glottis may be ascertained; and that spasm without inflammation, or with only subacute inflammation, is wanting in characters which are essential to the diagnosis of acute laryngitis. If a satisfactory laryngoscopic examination can be made, the diagnosis is demonstratively established.

Prognosis.—Acute laryngitis in the adult is a grave affection. The gravity, as already stated, depends in a great measure on the submucous infiltration. Cases without this contingency occur and may end favorably without very alarming symptoms. The suffering in these cases arises measurably from spasm. If the constant obstruction—*i. e.*, obstruction exclusive of that due to spasm—be sufficient to interfere greatly with respiration, the tendency is to a fatal result. A proportion of such cases will end fatally if life be not saved by timely surgical interference. The course of the disease in fatal cases is rapid. It has been known to prove fatal in seven hours. The duration rarely exceeds a week.

In young subjects this disease is less severe and less likely to prove fatal than in adults, notwithstanding the smaller size of the rima glottidis in early life, the difference being probably due to the fact that submucous products occur to a less extent in children.

Treatment.—The treatment of acute laryngitis embraces general and local measures. The general measures are those designed to lessen the intensity of inflammation, promote resolution, and the absorption of serous infiltration. The measures which may be employed for these ends are the same as in acute inflammation in other situations. It may be doubtful how far the ends are attainable; still, measures which are supposed to be in any degree operative, are not to be withheld in a disease involving so much danger as this. The employment of blood-letting is to be guided by the same principles as in other inflammations, but the evils and danger of abstracting blood are not as great as in certain other inflammations, for example, lobar pneumonitis, because there is not the amount of morbid effects to be recovered from, and it is therefore not so important to spare the vital powers for the processes of restoration. The danger in acute laryngitis, it is to be borne in mind, is not from the extent or degree of the inflammation, nor from the lesions which it may induce *per se*, but it is incidental to the seat of the inflammation. And, if a fatal result take place, the dying is by apnœa, not by asthenia. But in the use of blood-letting and other depressing measures, this consideration must be kept in view; the patient's strength is not to be so far diminished as to incapacitate for the prolonged muscular exertions which the labor of breathing may require. Blood-letting should never be practised after the occurrence of lividity of the prolabia and face. Under these circumstances, a fatal result would be hastened by abstracting blood.

The bowels should be moved efficiently by cathartics of the saline class. Nauseant or the direct cardiac sedatives are indicated as in other inflammations. Nauseant remedies should not be carried so far as to produce vomiting, which will add greatly to the distress and tend to aggravate the inflammation. If antimony be used, it should be given largely diluted, to avoid its local action on the throat.

Mercurialization may be advocated in this, as in some other affections, on the following ground: Although the antiphlogistic and sorbefacient powers of mercury have doubtless been heretofore greatly over-estimated, it is by no means certain that it exerts no remedial influence in these directions. So long, therefore, as there is room to suppose that it may be useful in any mea-

sure, it should be employed in an affection like this, which frequently tends rapidly to destroy life by apnœa. The general depressing effect and other evils of mercurialization are of little moment, provided the remedy prove in any degree useful in its influence on the local affection. If mercurialization be determined on, it should be induced early and rapidly, either by large doses guarded with opium, or by small doses repeated at short intervals, mercurial inunction being added.

Remedies to allay spasm and cough are indicated. The spasmodic element may be more or less prominent. Its degree of prominence is shown by the frequency and severity of the paroxysmal distress; whereas, the amount of obstruction due to the swelling and infiltration is shown by the labor of breathing in the intervals between the paroxysms or exacerbations. Opium and antispasmodic remedies are important in proportion to the amount of suffering from spasm, but opiates should not be carried so far as to blunt the perception of the want of breath. If belladonna be found to meet the indication, it is to be preferred to opiates.

In the foregoing remarks on the general measures of treatment, reference has been had especially to idiopathic or primary laryngitis. When the affection occurs as a complication of scarlatina, rubeola, or variola, and if it be associated with pulmonary or any other important disease, the same measures may not be admissible. This statement applies to bloodletting, mercurialization, and other depressing measures. Inflammation of the trachea frequently, if not generally, coexists, and bronchitis may be developed in accordance with the law respecting the extension of inflammation in the air-passages, namely, that it tends to travel downward, and but rarely upwards. Of course, the general symptoms, febrile movement, etc., will be increased in proportion to the extent of mucous surface inflamed.

The local measures of treatment embrace fomentations or poultices applied to the neck, with a blister, perhaps, applied over the sternum: and either the atmosphere of the apartment should be charged with steam, or the vapor of hot water inhaled by means of a convenient apparatus. The former is vastly more effective, and is, therefore, to be preferred. The application to the throat of compresses dipped in ice-water, and renewed at intervals of a few minutes, is a measure which may be tried with safety; and, if it afford relief, it may be often repeated, being continued as long as it is a source of comfort to the patient. Early in the disease it may act favorably as an antiphlogistic; and, afterward, it may afford relief by diminishing spasm. According to Cohen, it is indicated when the obstruction is caused in a measure by paralysis of the abductors.

Topical applications to the larynx may be made by means of a probang suited for that purpose. I have been assured by an intelligent medical student, who had experienced the disease, that he derived much temporary relief from the frequent introduction of a sponge saturated with a strong solution of the nitrate of silver. The application was repeated every three or four hours. The relief was probably due to the morbid sensibility of the part being blunted by the topical application, and the liability to spasm thereby lessened.

When the parts on laryngoscopic examination show much tumefaction above the vocal cords, Cohen advises scarification of the parts. If this measure be not practicable, or if it prove ineffectual, tracheotomy is to be employed, provided the obstruction becomes so great as to render danger of death imminent. Patients should never be allowed to die from strangulation for want of timely surgical interference. If the danger be purely or chiefly from apnœa, this operation will prove the means of saving life. The important question is—when is it to be performed? It should not be delayed until permanent lividity occurs, that is, lividity due to the obstruction caused by swell-

ing and infiltration irrespective of spasm. Persisting lividity denotes imminent danger, and impairs the probability of success from the operation. It is advisable not to delay either scarification or tracheotomy, or both, until lividity occurs, but to resort to surgical interference whenever the obstruction is sufficient to occasion sinking-in of the soft parts and retraction of the lower part of the chest in inspiration.

After convalescence is established, the recovery of the voice is slow, the pitch and quality remaining altered for some time.

The treatment of acute laryngitis in children, owing to its being a less severe and grave affection than in the adult, claims less vigorous treatment. Cases frequently, if not generally, do well with simple palliative measures. Emetics may be important in order to effect the removal of viscid mucus from the larynx. Death may be produced solely by obstruction due to the accumulation of mucus in this situation. It would hardly be supposed that the larynx may be so tolerant of obstruction from this source, that, occurring in a healthy child, efficient efforts of coughing would not be excited, and life be destroyed by slow apnœa; yet a case exemplifying the fact has fallen under my observation.

Subacute Laryngitis.

Subacute inflammation of the larynx is of frequent occurrence, either as preceding the development of bronchitis, or the inflammation not extending to the bronchial tubes. It characterizes certain cases of a common cold. The inflammation is of a low grade of intensity, and is not accompanied by submucous effusion. There is either hoarseness or aphonia, with cough, and an expectoration at first transparent and viscid, and afterward opaque, thick, and loose. There is no obstruction to respiration. Laryngeal spasm in the adult is rarely excited. There is little or no fever.

It is only important as involving some liability to an increase in the intensity of the inflammation or the development of the acute affection. But the liability to this is small. The measures of treatment are those indicated in cases of bronchitis or a "cold."

Subacute laryngitis exists in a certain proportion of the cases formerly included under the name croup. The croup-phenomena are due to spasm, the laryngitis being an unimportant element. This variety of so-called croup is unattended by danger, however violent may be the symptoms referable to spasm.

Chronic Laryngitis. Laryngeal Ulcers.

Chronic laryngitis occurs much more frequently than the acute form; it occurs, therefore, without having been preceded by acute laryngitis. Acute laryngitis, in fact, if it do not destroy life, ends in recovery, without eventuating in the chronic affection, and, on the other hand, in chronic laryngitis the inflammation rarely becomes acute.

In chronic inflammation the hyperæmia is less intense than in acute laryngitis. The mucous membrane has a grayish color, and often presents to view dilated veins. A mucous or purulent secretion coats its surface which is often granular from enlargement of the mucous glands. The vocal cords lose their smooth, glistening appearance, and are grayish or opaque. The flat epithelium covering them becomes thickened, and often, in other portions of the larynx, the normal cylindrical epithelium is replaced by the pavement variety. By development of new connective tissue the mucous membrane and submucous tissue often become thickened, and occasionally papillomatous

growths project into the cavity of the larynx. Instead of being hypertrophied, the mucous membrane in some cases is atrophied. Ulcerations more or less deep and extensive are frequent in chronic laryngitis due to specific causes.

In the majority of cases chronic inflammation in this situation occurs in connection with either syphilis or pulmonary phthisis. The localization of syphilis in this part is rare, so that the existence of chronic laryngitis constitutes presumptive evidence of the existence of phthisis. In cases of pulmonary phthisis with chronic laryngitis, it was formerly supposed that the latter precedes the former, and that the disease extends from the larynx to the lungs. The term *laryngeal phthisis* was used to distinguish the affection in these cases. Improvement in the means of detecting a tuberculous deposit in the lungs, however, has led to a knowledge of the fact that the laryngitis in these cases is secondary, the pulmonary disease being always first developed. The laryngeal ulcers which complicate pulmonary phthisis, are most frequently seated on the posterior surface of the larynx, just above the commissure of the vocal cords. In many cases a single small ulcer in this situation is found. This may, however, extend in depth and surface, and others may likewise appear. The vocal cords may be nearly destroyed by phthisical ulceration, and one or more small ulcers are often found on the epiglottis. The smaller ulcers are usually round, the larger ones have festooned borders. The edges are thickened. These ulcers are usually tuberculous.

While phthisical ulcerations most frequently begin just above the vocal cords, syphilitic affections are usually developed in the upper portion of the larynx. *Syphilitic laryngitis*, in general, follows syphilitic disease of the pharynx and base of the tongue. In the later stages of syphilis, laryngeal ulcerations, often of the most destructive character, if not properly treated, may be developed. These usually begin on the epiglottis, and extend downwards. They may attack the vocal cords, and even extend into the trachea. They are accompanied usually with much induration and thickening of the submucous tissues. When the ulcers heal, sometimes deforming cicatrices are formed, which may lead, especially on or about the vocal cords, to dangerous and even fatal stenosis.

Inflammation of the tissues immediately surrounding the laryngeal cartilages is called *laryngeal perichondritis*. Suppurative perichondritis is most frequently the result of syphilitic or phthisical ulcers in the larynx; it occurs as a very rare complication in infectious diseases of an asthenic type. The non-vascular cartilage suffers in its nutrition, and often becomes partly or wholly necrotic, so that loose pieces of cartilage, usually calcified or ossified, are found bathed in pus. If the collection of pus open into the laryngeal cavity, the dead pieces of cartilage may be coughed out. A necrosed fragment of cartilage has been known to become lodged in the glottis, and to cause death by suffocation. Sometimes the perichondrial abscess opens externally, and through the opening necrosed cartilage may be discharged.

The most characteristic of the symptoms of chronic laryngitis relate to the voice. It becomes either hoarse, husky, or stridulous, and it may be lost, that is, there is either difficulty of speech (dysphonia) or its extinction (aphonia). If aphonia exist, the patient speaks in a husky whisper. The extent to which the voice is affected is not a criterion of the extent to which the vocal organs are damaged by ulceration. Slight ulcerations and thickening may lead to great huskiness and even extinction of the voice. If notable hoarseness exist, more or less destruction of the vocal cords, enlarging the *rima glottidis*, may be suspected.

As regards cough, its prominence, as a symptom, varies in different cases.

It is modified like the voice, that is, it is either hoarse, husky, or stridulous. The expectoration, also, varies. It may be slight, or more or less abundant. Its characters may be those of mucus, muco-purulent matter, or pus. Not infrequently it presents bloody streaks, and it may be fetid. The bloody streaks and pus point to ulceration; the fetor points to caries of the cartilages. Cough and expectoration, however, it is to be borne in mind, are measurably due to the tuberculous affection of the lungs, with which the laryngitis is generally associated. Some cases of tuberculous laryngitis are characterized by violent paroxysms of cough, resembling those of whooping-cough, and vomiting is apt to occur during the paroxysms.

A marked difference in different cases relates to deglutition. In some cases the act of swallowing is attended with no inconvenience; but in a certain proportion of cases it is a source of great distress. The passage of food and drink causes pain, excites spasms of the glottis, thus occasioning distressing dyspnœa, and frequently liquids are returned through the nostrils. Patients are obliged to confine themselves to the blandest articles of diet, and even these are sometimes ingested with so much difficulty that death is hastened by innutrition. The difference, in different cases, depends on the situation of the ulcerations, these extending sometimes above the vocal cords and upon the epiglottis, where the ulcerated surface comes in contact with the food and drink in the act of swallowing, and sometimes being sufficiently below the top of the larynx to be secure from this source of irritation.

The diagnosis of chronic laryngitis is easy; the morbid characters of the voice at once indicate the affection. Its connection with pulmonary phthisis is to be determined by a physical exploration of the chest, together with an examination into the previous history and symptoms. If pulmonary disease be excluded, the syphilitic source of the affection is to be investigated. The affection may be regarded as idiopathic in cases in which both syphilis and phthisis can be excluded; but, as already stated, such cases are rare.

The prognosis in cases of chronic laryngitis will, of course, have reference to its pathological associations. Its connection with phthisis does not render the latter disease more rapidly progressive; on the contrary, the progress of the tuberculous affection of the lungs is, as a rule, more slow with, than without, this complication, provided it does not interfere with alimentation. Occurring in this connection, however, the laryngitis is rarely recovered from. The inflammation and ulcerations usually continue, but, if not, the voice remains permanently more or less impaired. Considerable improvement may take place in cases of tuberculous laryngitis, although the affection continues. Chronic laryngitis, dependent on syphilis, offers a better prospect of recovery. The voice, however, after recovery, will be likely to remain permanently affected.

In my experience, cases of tuberculous laryngitis have not presented notable embarrassment of breathing from obstruction. In not a few of the cases, however, of syphilitic laryngitis which I have seen, there has been sufficient stenosis to render respiration more or less labored; and, in some cases, obstruction threatened life by apnœa. In a number of cases which have come under my observation at Bellevue Hospital, the operation of tracheotomy has been resorted to, and, apparently, the lives of patients thereby saved. It has sometimes been resorted to more than once in the same case.

The treatment of chronic laryngitis, as regards general measures, will have reference to its pathological relations. In the great majority of cases, the treatment must be that indicated by the co-existence of pulmonary phthisis. If the affection be traceable to syphilis, the anti-syphilitic remedies are called for, namely, mercury and the iodide of potassium.

As regards local measures, counter-iritation over the neck by means of the

croton oil or small blisters is sometimes useful, even in cases of phthisis. The local treatment, however, relates more especially to applications to the affected part: that is, within the larynx. The injection of medicated liquids and the insufflation of remedies in the form of a dry powder have been employed for this purpose. Both these methods are objectionable owing to the difficulty of limiting the application to the diseased parts, and to the cough and spasm which they are liable to excite. A more satisfactory method is the introduction of a sponge attached to a probang properly curved.

Heretofore there has been much discussion respecting the feasibility of passing the sponge within the larynx, and there are those who still maintain that it is impracticable. It is true that the operation is extremely difficult, if, indeed, it be practicable, on the cadaver, and the scepticism of some as to the feasibility of the operation on the living body is based on this fact. But the enlargement of the glottis which takes place in the act of inspiration, divests the operation of the difficulty which attends its performance after death. It is during the act of inspiration that the introduction must be made. During the act, as is well known, foreign bodies of large size are sometimes drawn with the inspired breath into the air-passages. The sponge is passed into the larynx with proper knowledge and skill, but doubtless practitioners often deceive themselves, pushing the instrument into the œsophagus instead of the larynx.

The topical remedy most frequently applied by means of the sponge is the nitrate of silver. A strong solution is commonly used, namely, from one to two scruples to the ounce of distilled water. The sponge moistened by this solution is carried between and below the vocal cords. Spasm of the glŏttis occurs, and the liquid, being expressed from the sponge, comes into contact with the whole of the interior surface of the larynx. This application is sometimes beneficial, affording immediate and marked relief. It may then be repeated from time to time. In many cases, however, no relief is afforded, and in these cases, after a fair trial, it is useless to persevere in it.

Tracheotomy is to be resorted to in cases of syphilitic laryngitis whenever obstruction endangers life. The propriety of this operation as a means of promoting recovery has been advocated. For this purpose the opening is to be maintained for an indefinite period. The advantage consists in the arrest of the respiratory movements of the laryngeal muscles, which is a result of breathing through the trachea.[1] This measure has also been advocated in cases of laryngitis associated with pulmonary phthisis, the objects being complete rest of the larynx and the prevention of the passage of the matter of expectoration over the ulcerated surfaces. It has proved a useful measure in some reported cases.[2] To what extent it is useful or warrantable remains to be settled by further observations. An objection to it in cases of phthisis is the obstacle which a tube in the trachea offers to free expectoration. If found to be useful, its usefulness will probably be limited to the cases in which the laryngeal affection involves dysphagia, and in this way interferes with alimentation.

The laryngoscope has proved highly serviceable in the diagnosis and treatment of laryngeal affections. The nature and seat of lesions within the larynx may be thereby ascertained, and the knowledge thus obtained affords aid in judging as to the propriety of topical applications, and in showing the particular points at which they are to be made. The laryngoscope, in fact, may be said to have, in a great measure, transferred the interior of the larynx from the domain of medicine to that of surgery, by rendering this part open

[1] *Vide* article by Thomas Bryant in the Trans. Clin. Soc. of London, vol. i. 1868.
[2] *Vide* article by Dr. Beverley Robinson, Am. Journ. of Med. Sciences, April, 1879.

to inspection, and making the information thus obtained available for surgical operations. By inspection of the parts within the larynx, lesions may be excluded, and in this way laryngoscopy is of great practical advantage. The presence or absence of foreign bodies may by this means be ascertained. Inspection of the glottis is useful in order to determine whether paralysis of the laryngeal muscles exists or not. Moreover, the characteristic appearances on inspection may aid the experienced observer in differentiating syphilitic disease.[1]

Laryngitis with Fibrinous Exudation. (Membranous Croup.)

In Part First of this work (p. 38) the anatomical characteristics of the so-called croupous, diphtheritic and pseudo-diphtheritic inflammations have been briefly mentioned. It is important to distinguish between the anatomical signification of these terms and the clinical application of the names croup and diphtheria. In croup we may have diphtheritic as well as croupous inflammation, the difference depending chiefly upon the seat of inflammation. Decided as are the differences between membranous or true croup and diphtheria, as regards etiology and clinical history, essential points of difference in respect of their pathological anatomy have not, as yet, been established. In both diseases there is a fibrinous exudation. In croup the larynx is by preference attacked, in diphtheria the pharynx and sometimes the nasal passages; but croup is usually accompanied with fibrinous exudation in the pharynx, and diphtheria frequently with pseudo-membranous laryngitis. In both diseases the fibrinous exudation, when seated in the trachea or the lower portion of the larynx, is usually of the so-called croupous variety, and when seated in the pharynx or fauces of the diphtheritic or of the pseudo-diphtheritic variety. By so-called true or membranous croup, however, is understood a local disease characterized by fibrinous inflammation of the upper air-passages; by the name diphtheria, a general or constitutional disease with, in certain cases, a similar localization of the fibrinous exudation. In this article reference is had only to the affection heretofore known as true croup. Diphtheria is more appropriately considered under general diseases than under diseases affecting the respiratory system.

The term croup is of Scotch origin, and signifies strangulation. As already stated, it has been used, in a comprehensive sense, to signify a variety of affections in children, characterized by a peculiar shrill, barking cough, called the croupal cough, and by difficulty in breathing. These symptoms may accompany in children simple acute or subacute laryngitis, and also spasm of the glottis without laryngeal inflammation. To such cases the name *false croup* has been applied in distinction from *true croup*, the latter term being employed only for the pseudo-membranous variety of inflammation.

The extent of the fibrinous exudation varies in different cases. The exudation, in the form of a false membrane, is found in the larynx and trachea; it is also present, as a rule, in the pharynx, on the tonsils, soft palate, base of tongue, or epiglottis. The larger bronchi are often involved, and in rare instances those of small size. The larynx may be primarily affected, or the false membrane may appear first in either the pharynx or the trachea. The false membranes are whitish or grayish, or brownish-red from admixture with blood. They vary greatly in extent, thickness, and consistency. On the mucous membrane of the pharynx or fauces the fibrinous exudation appears

[1] Cohen's treatise on Diseases of the Throat, etc., embodies the important facts pertaining to the laryngoscope. Second edition, 1879.

usually in patches; in the larynx, the favorite seat of the exudation is the vocal cords which are often uniformly coated and sometimes so thickly that the glottis is nearly occluded. The false membrane may be expectorated in the form of shreds, or of tubular casts of the larger bronchi, or, rarely, as solid cylinders from the small bronchi. The membrane, when recent, is of tolerably firm consistence; it may be found on autopsy, however, as a soft, pultaceous mass coating the mucous membrane. In the trachea and bronchi it can, as a rule, be readily stripped off from the subjacent mucous membrane; in the larynx it can also often be removed without tearing the mucous membrane, but it is usually closely adherent on the epiglottis and true vocal cords; in the pharynx and on the soft palate also it is intimately connected with the mucous membrane. In the bronchi, trachea, and lower portion of the larynx, the fibrinous exudation is of the so-called croupous variety, that is, the false membrane consists chiefly of fibrillated fibrin holding in its meshes pus-cells, red blood-corpuscles, and sometimes epithelial cells; it sits directly upon the basement membrane in most places, the epithelium being absent; the mucous membrane itself is swollen, hyperæmic, and contains a variable number of emigrated white blood-corpuscles and sometimes ecchymoses, but no fibrinous exudation. On the epiglottis and in the other parts of the throat, the exudation is often of the pseudo-diphtheritic variety, that is, the false membrane cannot be detached without loss of substance from the subjacent mucous membrane, but there is no fibrinous material in the mucous membrane itself. The exudation, however, may be diphtheritic, that is, the fibrinous substance is present, not only upon the surface, but also in the tissues of the mucous membrane. As has been explained in Part First, the fibrinous material in the diphtheritic and pseudo-diphtheritic forms of inflammation consists, in part, of fibrillated fibrin and in part of epithelial, pus and connective tissue-cells which have undergone the peculiar metamorphosis called coagulation-necrosis. Bacteria in the form of micrococci, or, according to Klebs, of monads, are often found as colonies in the false membranes. It is not proven that they are more than accidental admixtures. During the course of the disease the pseudo-membranes may be repeatedly exfoliated, and new ones formed in their place.

The lungs, after death from fibrinous laryngitis, often present spots of atelectasis, also an emphysematous condition, especially of the upper lobes, hyperæmia, and sometimes lobular pneumonitis, rarely the lobar form.

Clinical History.—The symptomatic phenomena in this variety of inflammation, at the outset, are the same as in simple laryngitis. The local and general symptoms may not be as marked as in cases of simple acute laryngitis. The disease is often supposed to be nothing more than a common cold. There is more or less cough, and the cough is hoarse or barking; hoarseness or huskiness of the voice exists, and moderate fever. The symptoms denoting gravity of disease arise from obstruction due to the exudation, in connection with swelling of the glottis and the occurrence of either spasm or paralysis of the laryngeal muscles. One, two, or three days may elapse before the disturbance of respiration is sufficient to create any apprehension. Not infrequently the general symptoms do not prevent the child from being up and engaging in play, even after a certain amount of obstruction has taken place. The obstruction due to the exudation and swelling is shown by labored breathing in both acts, and by dilatation of the nostrils. These evidences may be apparent before the obstruction is sufficient to occasion suffering from dyspnœa. The additional obstruction due to laryngeal spasm, is shown by the dyspnœa which occurs in paroxysms or exacerbations. Spasm may be more or less prominent as an element of this form of disease; as a rule, it is

far less prominent than in the affections heretofore known as false croup. Hence, of all the varieties of so-called croup, this, in its development and early progress, is the least likely to excite alarm.

As the disease advances, the obstruction is increased. The labor of breathing becomes greater, and is attended with manifestations of distressing dyspnœa. The current of inspired air is insufficient for the free expansion of the lungs, as denoted by contraction of the lower part of the chest together with sinking in of the soft parts above the clavicles and sternum in the act of inspiration. The cough becomes stridulous and abortive. The voice or cry is reduced to a husky whisper. The face is congested; an expression of anxiety and distress is marked. More or less fever continues. The sufferings are increased at variable intervals in proportion as the spasmodic element is prominent. If life be prolonged, the cough at length becomes loose, and portions of the false membrane are expectorated from time to time. The obstruction may then gradually decrease and recovery take place. If the disease prove fatal, the mode of dying is by slow apnœa; but not infrequently the suffering from dyspnœa diminishes toward the close of life, and the labor of breathing may be so far lessened as to excite delusive hopes of improvement. Convulsions occasionally occur toward the close of life..

Niemeyer considered as a cause of obstruction, in certain cases, paralysis of the posterior crico-arytenoid muscles. As a result of paralysis of these muscles, dilatation of the glottis does not take place in inspiration, and obstruction during the inspiratory act occurs as after section of the recurrent laryngeal nerves in the experiments to illustrate the respiratory movements of the glottis. The author just named stated that he has ascertained the fact of immobility of the glottis in cases of the disease by laryngoscopic examination. In so far as the obstruction is due to this cause, it will be manifested in the inspiratory act. A case under my observation seemed to exemplify obstruction from this cause. The obstruction was limited chiefly to inspiration, and was accompanied by a laryngeal sound suggestive of a sucking inward of the glottis. In this case the obstruction occurred after the laryngitis had existed for six days, no obstruction having previously existed; and after its occurrence it increased so rapidly that in six or eight hours tracheotomy was required. The age of the patient, three years, rendered the occurrence of œdema of the glottis improbable. Prof. J. Lewis Smith has indicated another important, incidental circumstance which increases the interference with respiration, namely, the accumulation of muco-pus in the trachea and bronchial tubes, the presence of the false membrane in the larynx and the feeble expiratory efforts preventing expectoration. He has observed a case in which this seemed to be the cause of death. The danger from accumulation below the larynx is, of course, incidental to the cases in which bronchitis co-exists.[1]

Pathological Character.—Fibrinous exudation occurs exceptionally in inflammation of a mucous structure. It denotes a peculiar kind of inflammation, and, probably, represents an underlying, special, constitutional morbid condition. This peculiarity of the inflammation, thus, belongs to it from the beginning. It is not evidence of intensity of the inflammation; on the contrary, the inflammation in this variety of laryngitis is less intense than in the simple acute variety. Simple acute laryngitis, therefore, has no tendency to eventuate in fibrinous exudation. And in the other affections of the larynx which have been commonly embraced under the name croup, the form of disease under consideration, distinguished as true or membranous croup, is not liable to supervene.

[1] *Vide* Diseases of Infancy and Childhood, by J. Lewis Smith, M.D., 3d ed., 1879.

Causation.—This form of disease is generally met with in young children, but rarely in infantile life. The age, in the great majority of cases, is between two and seven years. The disease, however, may occur at any period from birth to the age of two years, and at any period after seven years. Boys are oftener affected than girls. It occurs oftener in some situations than in others; a cold, humid, changeable climate contributes to its occurrence. Cases occur oftener in the spring and autumnal months than at other portions of the year. Happily, it is everywhere a rare disease, excluding, it will be borne in mind, its occurrence as a complication of diphtheria. It may occur as a primary or a secondary affection. Exclusive of its occurrence in diphtheria, it is sometimes developed in connection with the affection of the pharynx in scarlatina. It occasionally follows measles. The inflammation and exudation, as already stated, generally involve more or less of the pharynx, the point of departure being, in some cases the larynx, and in other cases the pharynx, oftener the latter.

Diagnosis.—Considering the great fatality of this disease, the diagnosis is of great importance with reference to the prognosis and treatment. It is to be discriminated from simple acute laryngitis, from subacute laryngitis with spasm, and from a purely spasmodic laryngeal affection which is presently to be considered. In each of these affections laryngeal spasm is more or less involved, and the character of cough and respiration distinguished as croupal, is chiefly attributable to that element. The spasmodic element is more likely to be prominent, especially at the outset, in the other affections just named, than in this affection; in other words, this, the so-called true croup, presents the croupal phenomena less marked than either of the forms of the so-called false croup. The insidious development of this disease, which alone of the affections formerly embraced under the name croup is attended with danger, renders it liable to be overlooked until the disease has progressed so far as to give rise to serious obstruction.

As contrasted with the other affections just named, the slow, insidious development is one of the points involved in the differential diagnosis. In the so-called catarrhal and the spasmodic variety of croup, the croupal phenomena occur suddenly and violently, the attack almost always being in the night. When such an attack occurs without having been preceded by cough, febrile movement, and alteration of the voice, it is almost certain that the affection is not true croup. Alteration of the voice is an important diagnostic feature. This will distinguish it from a purely spasmodic affection, but not from simple laryngitis, either acute or chronic; the voice, however, is affected in a more marked degree in laryngitis with fibrinous exudation.

The presence of fibrinous exudation about the epiglottis, and more or less within the pharynx, is a point of great importance in the differential diagnosis. With reference to this point, the observations of Ware are valuable. In his analysis of cases of the several varieties of croup, out of 33 cases of true croup, *i. e.*, laryngitis with exudation, a pharyngeal exudation was observed in all save a single case. On the other hand, of 45 cases of the affections included under the head of false croup, an exudation within the pharynx was sought for and found to be wanting in every case. Of 19 cases observed by Meigs with respect to this point, in all but three an exudation occurred in the pharynx either before or after the development of the laryngitis. In view of these facts, the presence of an exudation within the pharynx, taken in connection with the symptoms which denote laryngitis, renders it extremely probable that exudation exists within the larynx. It is to be borne in mind, however, that the pharyngeal exudation is sometimes wanting, and that its absence in the larynx cannot be inferred from its non-existence in the pha-

rynx with as much positiveness as its presence in the larynx is to be inferred from its existence in the pharynx.

In order to render the diagnosis positive, if the co-operation of the patient can be obtained, the laryngoscope should be employed. The existence of the disease is, of course, demonstrated if the intra-laryngeal space can be inspected.

In the progress of the disease, if it do not destroy life, the discovery of patches of false membrane in the matters expectorated should be considered as the only reliable test of the correctness of the diagnosis. The non-observance of this test has led not infrequently to cases of simple laryngitis being regarded as cases of laryngitis with fibrinous exudation successfully treated.

With capillary bronchitis this affection need never be confounded. In capillary bronchitis the respirations are frequent, panting, gasping; in laryngitis with exudation the acts are labored and difficult, and, as a rule, not notably frequent. The embarrassed, noisy breathing, especially during sleep, in cases of enlargement of the tonsils, may, at first, suggest the affection under consideration; but it is readily excluded by the absence of the croupal cough and of hoarseness.

Prognosis.—The tendency of this disease is to a fatal result. Of twenty-two cases analyzed by Ware, nineteen proved fatal. Even if the affection be limited to the larynx, and uncomplicated, it will destroy life in the great majority of cases, if patients be not saved by surgical interference. The danger is, of course, increased, if the affection extend to the bronchial tubes, and in proportion as it extends towards the smaller tubes. Not infrequently broncho-pneumonia exists as a complication, and this, of course, augments the danger. The duration of the disease, in fatal cases, is usually from four to six days. In a small proportion of cases, it kills in less than four days, or life is prolonged beyond six days. If recovery take place, convalescence is reached after a gradual improvement, and is generally slow, the voice remaining more or less affected for a considerable period.

Treatment.—Under measures of treatment heretofore relied upon, this disease proved fatal in the vast majority of cases. The treatment was based on the supposition that the exudation depends on the intensity of the inflammation, and, with a view to reduce this intensity, the measures known as antiphlogistic were actively employed. They have been employed sufficiently to show that they are not successful; and, if they do not do good, they can hardly fail to do harm. With a view to the proper objects of treatment, it is to be considered that cases are rarely seen prior to the occurrence of exudation, and that the prevention of exudation, therefore, is not the end to which therapeutical measures are to be directed. It is also to be considered that, exudation having taken place, recovery is effected by the separation of the false membrane, and that its separation takes place as a result of a suppurative process beneath it, this process requiring several days. These facts being considered, the rational objects of treatment are to prolong life until the separation of the false membrane can be effected, and to promote the process by which this is effected.

Depletion by bloodletting or other means is not indicated. By reducing the strength of the patient, it conflicts with the first object, namely, the prolongation of life. On the contrary, the strength is to be supported, as far as practicable, by concentrated nourishment, and the judicious use of alcoholics. Emetics, which have heretofore been used excessively in this disease, are to be employed with circumspection in order not to conflict with the first object. They have been given, and frequently repeated, in order to relieve spasm,

and it is undoubtedly true, that, for a short period after their operation, the breathing is comparatively easy; but this end may be attained by other measures less objectionable on the score of depressing the powers of life. Another purpose of emetics is to aid in detaching the false membrane. But it is useless to give emetics for this purpose until the exudation has been loosened by the process of suppuration. Emetics, however, are not to be entirely withheld. In children they compensate for the want of voluntary efforts of expectoration. They may aid in the expulsion of the false membrane when it becomes detached. A fact stated under another head in this chapter is not to be lost sight of, namely, the tolerance of the larynx in young children of an accumulation of mucus sufficient to occasion fatal obstruction. Emetics, then, may be given from time to time, but not too frequently, and the emetic substances used should be those which excite prompt and efficient vomiting without producing prolonged nausea and depression. This will exclude antimony. Ipecacuanha, powdered alum, turpeth mineral, and the sulphate of zinc, are among the articles which may be selected. Of these articles, the turpeth mineral acts promptly and efficiently, without much depression or nausea. It is to be borne in mind that the accumulation of mucopus in the trachea and bronchial tubes, in certain cases, furnishes an indication for the use of emetics.

Anodyne remedies are indicated to allay spasm. Opium, however, is to be given with great circumspection. Belladonna and other of the narcotics, if they be found to answer, are to be preferred. Mercury is admissible on the ground stated under the head of simple acute laryngitis, that is, the objections to its use are not to be taken into account in so dangerous a disease as this, so long as there is any ground to suppose that it will do any good.

In the early part of the disease, cold applications to the neck may be tried, as in the treatment of simple acute laryngitis. These, as in cases of the latter form of laryngeal inflammation, have reference, *first*, to lessening the intensity of the inflammation, that is, to an antiphlogistic effect, and, *second*, to a sedative effect as regards spasm of the laryngeal muscles. To employ cold efficiently, compresses dipped in ice-water may be applied and removed at intervals of a few moments. The continuance of these applications and their repetition are to be determined by the relief which they appear to afford. They should not be persisted in if the patient resolutely resist them, or if they do not seem to give relief. Niemeyer advocated cold applications in this disease; their value was, however, inculcated by the late Prof. Peaslee, of this city, in 1854.[1] Prof. Peaslee considered the continuous application of cold essential in order to secure its full effect. Prof. J. Lewis Smith employs, instead of compresses dipped in cold water, crushed ice surrounded by oiled silk.

Topical measures of an opposite character have reference to the second object, namely, promotion of the process by which the false membrane is separated. The neck may be enveloped in a poultice or the water dressing, for the same reason that these are deemed useful in phlegmonous inflammation, namely, to hasten suppuration. But the most efficient topical application is the inhalation of steam, and the best method is to charge the atmosphere of the room with as much of it as possible. In a room at a temperature of 80° or 85°, filled with steam, patients are free from spasm, and breathe with comparative ease. I have observed cases in which patients passed safely through the disease, the inhalation of steam being the chief measure relied upon.

From the fact that pseudo-membranous exudations are rapidly dissolved in lime-water, the inhalation of spray from lime-water has been resorted to as a

[1] *Vide* American Medical Monthly, 1854.

means of removing the false membrane from the larynx and trachea, and cases in which this treatment was successful have been reported. Slaking quicklime is an effective mode of securing this object, and, at the same time, furnishing a warm, pleasant vapor. Breathing pure oxygen from time to time, and diffusing it in abundance in the atmosphere of the room, affords marked relief of dyspnœa. In the case of a child of my late colleague, Prof. Elliot, steam from boiling water, the lime vapor produced by slaking a barrel or more daily of quicklime in the room, the inhalation of oxygen which the child soon desired from the relief derived from it, and keeping the atmosphere of the room charged with oxygen from a continuous stream of the gas, were the only measures employed, in addition to alimentation and a little alcoholic stimulant, excepting a single emetic of turpeth mineral when the symptoms and signs denoted loosening of the laryngeal false membrane. The child passed through the disease not only safely, but without great suffering. In another case under my observation, the same measures were relied upon, and with the same success.

The topical application of a strong solution of the nitrate of silver was advocated by Horace Green. The introduction of the sponge probang into the larynx of the child is difficult, owing to the small size of the glottis, and, frequently, the want of co-operation on the part of the patient; yet it may be effected. I have witnessed a recovery in a case in which this was the chief measure employed. The applications were made twice daily. When the false membrane is loosened, the introduction of the sponge may be useful mechanically, detaching the membrane and pushing it below the glottis, thus leading to its expectoration.

Lastly, the propriety of tracheotomy, in cases of this affection, is to be considered. For statistics bearing on this subject the reader is referred to treatises on the diseases of children, and articles in medical periodicals. The propriety of the operation hinges, not on the number of cases in which it has proved successful, but on the answer to the question whether lives are saved by it. Now, it cannot be doubted that patients with this disease have been snatched from impending death by opening the trachea. It is, therefore, not only justifiable, but the practitioner is bound, if possible, not to allow patients to die from suffocation for the want of this operation. Of course, the duty of resorting to it is the more imperative the greater the probability of its success; and a fair examination of statistics will show that not a very small proportion of those who would otherwise die may be rescued by it.

The success of tracheotomy depends much on its timely performance. Its failure in many cases is attributable to its having been too long deferred, but it has proved successful repeatedly as a *dernier ressort* under the most unpromising circumstances. As soon as the persisting obstruction, that is, the obstruction due to the exudation, associated perhaps with paralysis of the dilating muscles of the glottis, compromises respiration sufficiently to render it probable that the patient's life will not be prolonged until the separation of the false membrane can take place, the operation is called for. Its success, doubtless, depends much on the manner of its performance, and the subsequent management. For information on these points the reader is referred to surgical works.[1]

Sir William Jenner has pointed out an objection to a premature performance of tracheotomy, namely, the effect of the operation on the ability to cough. In an efficient act of coughing, first, a deep inspiration is taken and the glottis closes; then by means of forcible expiratory efforts the current of expired air, dislodging from the bronchial tubes their contents, carries them

[1] Cohen's Treatise on Diseases of the Throat, etc., may be consulted, 2d ed., 1879.

into the trachea, and, the glottis suddenly opening, expectoration is effected. Now, with an opening in the trachea, an efficient act of coughing cannot take place; hence, there is a greater liability to accumulation in the bronchial tubes than if tracheotomy had not been performed. The danger from this effect of the operation thus relates to the bronchial tubes in the cases in which bronchitis is associated with the laryngitis.

If the operation prove unsuccessful, it diminishes greatly the suffering from obstruction, and is fully justifiable with a view to euthanasia.

Œdema of the Glottis.

This name denotes a serous or, more frequently, a sero-purulent effusion in the submucous areolar tissue above the vocal cords. In the majority of cases, therefore, œdema of the glottis is an inflammatory affection. The effusion is situated chiefly in the ary-epiglottic folds, about the ventricle of Morgagni, and the base of the epiglottis. On the vocal cords the mucous membrane is too intimately adherent to the subjacent dense fibrous tissue to admit of submucous effusion. The ary-epiglottic folds and adjacent tissue are swollen, soft, and project from each side, as two semi-transparent, gelatinous tumors, as large as, or even larger than, a pigeon's egg, which, lying upon the glottis, are sucked inward with the inspiratory act, and thus occasion obstruction. The current of air in expiration separates and pushes the tumors upward, so that in cases of œdema without laryngitis there is little or no obstruction in the expiratory act. Upon cutting into the œdematous tissue a serous or sero-purulent liquid escapes. It is rare for pus-corpuscles to be so numerous that the effusion is distinctly creamy and purulent. In most cases of Bright's disease complicated with œdema glottidis, the effusion is thin and watery, with comparatively few blood-corpuscles. The œdema usually exists on both sides, but it is sometimes unilateral.

When œdema of the glottis is due to the inflammation of the mucous membrane in proximity to the seat of the effusion, it is analogous to the subcutaneous œdema which accompanies inflammation of the skin in situations where the areolar tissue beneath is abundant and lax, as, for example, around the eyes and on the penis—the collateral œdema of Virchow. This so-called collateral œdema is, however, always of inflammatory origin (see Part First, pp. 35 and 37).

As causes of œdema glottidis may be mentioned laryngitis, pharyngitis, tonsillitis, retro-pharyngeal and cervical abscess, injuries to the neck, particularly cut-throat wounds, swallowing irritant poisons, such as ammonia, sulphuric acid, etc., erysipelatous inflammation of the neck. It also occurs in connection with certain general diseases, especially those complicated with laryngitis, as typhus and typhoid fevers, smallpox, septicæmia, phthisis, and both the acute and chronic forms of Bright's disease. It has been attributed to the action of cold. It probably never occurs as an idiopathic affection. It is important to add that it may occur as the first and only dropsical affection connected with disease of the kidneys. Its gravity, and the necessity of prompt and efficient interference, render it vastly important to appreciate the pathological condition, and to recognize its existence.

The occurrence of the œdema may be sudden, and life be destroyed in a few hours, or even minutes.[1] In a case occurring in connection with mild pharyngitis, the suffering from obstruction was developed during the night, and the patient, leaving his apartment to seek for aid, fell upon the floor and

[1] A case is reported in *Guy's Hospital Reports*, April, 1855, which terminated fatally within five minutes after difficulty from obstruction was experienced.

died before any assistance could be rendered. In a case in which it occurred in connection with tonsillitis, the patient was left to sleep in an apartment by himself, there being no difficulty of breathing, and, in the night-time, a relative in an adjoining room was awakened by his noisy breathing. He was found to be unconscious, and, although medical aid was promptly called, and the trachea opened without delay, the operation was too late to prevent a fatal result.

Difficulty of breathing, due to obstruction at the glottis, is a prominent symptom. This is associated with a sense of a foreign substance at the seat of the obstruction, and a strong disposition to hawk and swallow. The diagnostic point relating to the difficulty of breathing is, the inspiratory act is alone, or chiefly, obstructed, expiration being free. The inspiration is arrested before it is completed, being, as it were, suddenly cut short, and both the inspiration and expiration are accompanied by marked stridor. If laryngitis do not co-exist, the voice is devoid of hoarseness or huskiness. This will serve at once to exclude laryngitis. I have met with a case, ending fatally, in which there was no hoarseness nor huskiness of the voice, and no appearance of laryngitis after death. The diagnosis may be made positive by means of the touch. With the forefinger introduced into the mouth, carried to the base of the tongue, and applied below the epiglottis, the œdematous tumors may be distinctly felt. This diagnostic test, enunciated by Tullier in a thesis submitted to the Faculty of Medicine, in Paris, in 1815, appears to have been lost sight of until attention was called to it a few years since, by the late Dr. Gurdon Buck, of New York.

If the embarrassment of breathing be not too great to permit a satisfactory laryngoscopic examination, this will render the diagnosis positive. The tumors may sometimes be seen by depressing the tongue, without the aid of the laryngoscope.

Statistics have heretofore shown a large fatality. Bayle found that in 17 cases only 1 recovery took place. Of 40 cases collected by Valleix, 31 were fatal. Of 168 cases collected by Sestier, 127 died. With a correct appreciation of the pathological condition, a prompt recognition of it, and timely surgical interference, many, if not most, patients may be saved. It is fair to attribute the large proportion of fatal cases heretofore to either an imperfect knowledge of the affection, delay in the diagnosis, or want of promptness in resorting to efficient interference.

The affection kills by apnœa. The object of treatment is to prevent suffocation, and if the obstruction be sufficient to occasion much labor of breathing, lividity, etc., no time is to be lost in efforts to obtain relief by medication. Either the larynx or trachea must be opened, or the method of scarification, as practised by Dr. Gurdon Buck, must be resorted to. Buck's method consists in introducing a curved bistoury, properly guarded, into the mouth, carrying it below the epiglottis guided by the left index finger, and scarifying on both sides, so as to give exit to the effused liquid. The scarification may be repeated if required.[1]

My personal observation of Buck's operation is based on a single case, in which it was employed by a surgical colleague at a moment's notice, and without the advantage of a prior acquaintance with it. The difficulty in the way of its performance is greater than might be supposed. The increase of suffocation caused by introducing the fingers into the mouth, the movements of the larynx incident to the labored breathing, and the acts of vomiting

[1] *Vide* Trans. Am. Med. Association, vols. i. and iv. Several cases successfully treated by this method are reported by Dr. Buck. Cohen (op. cit.) has used, with success, for scarification, a common gum lancet.

which are excited, render it not easy to deliberately scarify the œdematous parts. In the case referred to, the result was unfortunate. The tumors were not sufficiently scarified, but wounds were made which led to hemorrhage and the flow of blood into the air-tubes. Tracheotomy was subsequently performed, but too late to save the patient. The case is referred to in order to enforce the importance of being prepared to meet with more difficulty than might be anticipated. Without assuming to adjudicate in a matter which is purely surgical, I am led to think that the simpler, as well as the more effectual, operation is to open the larynx or trachea. Niemeyer stated that in some cases the finger-nail will suffice to open the œdematous tumors. Strong pressure with the finger has succeeded.

A case at Bellevue Hospital exemplified the importance of opening the trachea before the obstruction threatens immediate death. A patient was suffering considerably from difficulty of breathing, but, as was decided, not sufficient to require laryngotomy. The House Physician, however, made every preparation to perform the operation at an instant's notice. Suddenly the difficulty of breathing increased and the physician was in a few moments at the bedside, but too late to save the patient. The liability to a very rapid increase of obstruction proving quickly fatal, is to be considered in deciding upon the propriety of opening the larynx or trachea. The operation may be advisable, as a precautionary measure, even if life be not at the moment threatened, when the practitioner cannot remain with or near the patient until danger is passed. In the event of a physician being summoned to a case in which life is momentarily in danger, and when appropriate surgical instruments are not at hand, the larynx or trachea should be opened at once, without dissection, by a pocket knife.

Œdema of the glottis rarely occurs in infancy or childhood, the reason probably being that the areolar tissue at the situation where the œdema occurs is less abundant and loose in young subjects than after puberty. The period of life in which it is most apt to occur is between the ages of 20 and 40. It occurs much oftener in men than in women.

Œdema in very rare instances occurs below the vocal cords. This is distinguished as subglottic œdema. Its occurrence in this situation is not determinable by the touch. The diagnosis can only be made by means of the laryngoscope. Scarification is not practicable. Tracheotomy is indicated under the same circumstances as in cases of obstruction from œdema above the cords. The obstruction calls for this operation although the diagnosis of subglottic œdema may not have been made.

Spasm of the Glottis.

Spasm of the muscles closing the glottis is an important element in most of the affections of the larynx which have been considered. To this element are attributable the croupal cough and the paroxysms or exacerbations of dyspnœa in simple acute and subacute laryngitis in children, and in laryngitis with fibrinous exudation. But spasm occurs also as a purely functional affection, that is, irrespective of inflammation or lesion within the larynx. It is an element of several of the functional affections of the nervous system (neuroses) to be hereafter considered, namely, hysteria, epilepsy, epileptoid convulsions, rabies, and tetanus. Occurring irrespective of these connections, it may be reckoned among the functional affections of the larynx.

Spasm occurs in young children, affecting the respiration without inducing cough. This is the pathological condition when infants are said to have fits of "holding the breath." Respiration is arrested until the face becomes congested and livid, and, when the spasm relaxes, the inspiration may be sonorous, as in pertussis. In some children these paroxysms occur more or less

frequently. They are sometimes accompanied by carpo-pedal spasm. Convulsions may occur. Death may take place in a prolonged paroxysm, or in consequence of repeated paroxysms in rapid succession. I have known an instance of this kind. The affection is commonly known as *laryngismus stridulus*. From a fancied connection with enlargement of the thymus gland persisting after birth, it has been called *thymic asthma*.

This affection is purely neurotic. It involves a peculiar susceptility to spasm in the laryngeal muscles. This susceptibility may be incident to a certain period, as during weaning or dentition, but, in some cases, it appears to be an idiosyncrasy of infantile life. When the predisposition exists, paroxysms are liable to be excited by various causes acting physically and mentally. This susceptibility is sometimes observed in different children of the same family, a fact in confirmation of its innateness.

During a paroxysm, it is customary to employ means to produce a strong impression on the surface, as slapping the back or sprinkling cold water on the face. A ready and effective mode of arresting a paroxysm is to introduce a finger into the throat. The treatment otherwise involves the removal of all local causes of irritation, such as the distension of the gums and the retention of fecal matter, avoidance of causes inducing mental excitement, and measures to invigorate the system.

Spasm of the glottis occurring in children over two years of age, accompanied by laryngeal irritation and cough, is a frequent affection, known as *spasmodic croup*. A child is suddenly attacked during the night, having, perhaps, gone to bed apparently in perfect health. The breathing is labored and sonorous, the cough presents, in a marked degree, the shrill, ringing, croupal character. Great alarm is produced, and the physician is sent for in urgent haste. The surface of the body is cool; the pulse is small and perhaps not accelerated; the voice or cry is not hoarse nor husky as in laryngitis; the affection, in short, is purely spasmodic. It is unattended by danger. When the violent symptoms are relieved, respiration is found to be unobstructed. There is no liability to its eventuation in so-called true croup, that is, to laryngitis with fibrinous exudation. It is to be discriminated from the latter affection. The points involved in this discrimination are as follows: The abruptness of the attack, which is not preceded by symptoms denoting laryngitis; the violence of the attack, in this respect differing from so-called true croup; the absence of hoarseness or huskiness of the voice, of febrile movement, and of fibrinous exudation in the pharynx; and, finally, the speedy and complete relief. The paroxysms may recur for two or more successive nights.

The treatment consists of a mild emetic, if there be reason to suppose that the stomach is overloaded, a hot foot-bath, and warm fomentations to the neck. These measures are uniformly successful. The treatment of these cases is sometimes needlessly active, under the impression that a serious affection is threatened; and practitioners are apt to congratulate themselves and the friends of the patient on their success in preventing true croup.

Spasm of the glottis may occur as a functional affection in the adult. It is occasionally incidental to hysteria, and may simulate, as regards some of the symptoms, laryngitis, or œdema of the glottis. The diagnostic points are as follows: The co-existence of hysterical phenomena; the absence of huskiness or hoarseness of the voice; intermittency of the difficulty of breathing; the speedy relief obtained by anodyne remedies, and the sudden development of the affection. I have been consulted in several cases in which spasm of the glottis occurred in male adults without any evidence of disease within the larynx or of intra-thoracic disease.

The measures of treatment are anodyne or antispasmodic remedies for im-

mediate relief, and afterward those indicated by the general condition, and those employed in analogous nervous affections.

Spasm of the glottis may be occasioned by irritation of the recurrent laryngeal nerve from the pressure of a tumor or other causes. It is one of the symptoms of aortic aneurism, and, occurring in a person over forty years of age, it should always excite a suspicion of aneurism. I have reported a case of aortic aneurism in which the life of the patient was destroyed by frequently recurring paroxysms of laryngeal spasm.[1]

Nervous Cough.

The term nervous cough is used to designate a neuropathic disorder characterized by a dry, peculiar cough occurring without laryngitis, bronchitis, or any pulmonary affection. It may be noticed with propriety among laryngeal affections, inasmuch as the distinctive character of the cough relates to the larynx. In most of the cases which I have seen, the cough has had a peculiar barking tone, and the pitch has been low, showing that the glottis was dilated at the instant of coughing. In some cases, however, the tone is shrill and the quality of sound croupal, showing spasm of the glottis. In a case recently under observation, the cough consisted of a single, short, hoarse bark, often repeated several times in a minute. The cough is sometimes in paroxysms, having a resemblance to those of whooping-cough. The peculiar sound of the cough, together with its frequent recurrence, and sometimes its violence, renders it distressing to those whose sympathies are excited, and annoying to others. Cohen, who observed the movements of the glottis in a well-marked case by means of the laryngoscope, states that the vocal cords came together with force and suddenly separated at the instant of the cough.

This disorder rarely occurs in males. It is often associated with more or less of the symptoms embraced under the name hysteria. The cough has been called *tussis hysterica*, and it is usually included, by medical writers, among the diversified hysterical manifestations. It occurs chiefly in chlorotic girls. I have known it to occur before the age of puberty. It is apt to persist for a considerable period.

The diagnosis is to be based on the peculiarity of the cough, its dryness, except that the acts of coughing, if frequent and violent, may occasion some mucous expectoration, and the negative result of careful physical explorations of the chest. The diagnosis is strengthened, on the one hand, by the co-existence of anæmia, and of hysterical phenomena, and, on the other hand, by the absence of rational symptoms pointing to phthisis. The laryngoscope should be employed in order to render positive the exclusion of other laryngeal affections.

The indications for treatment relate to anæmia, if it exist, and to other morbid conditions affecting the nervous system. Tonic remedies, a nutritious diet, out-of-door life, and, in short, invigorating measures are indicated. In addition to chalybeates, may be mentioned quinia, small doses of strychnia, and the preparations of zinc as appropriate remedies. Hygienic measures, however, are of the first importance. A change of climate is sometimes advisable if other measures fail. A sea-voyage proved effective in a case under my observation, after a long persistence of the cough in spite of various measures of treatment. As palliatives for the cough, antispasmodic remedies may be prescribed, but opiates are not advisable.

This is one of the affections which may be induced by involuntary imitation. Cohen states that, within his knowledge, a school for girls was suspended in consequence of the large number of cases.

[1] American Medical Times, 1865.

Nervous Aphonia. Paralysis of Laryngeal Muscles.

Loss of voice, or aphonia, is incidental to the varieties of laryngitis which have been considered. But it occurs when not dependent either on inflammation or lesions within the larynx; in other words, as a functional affection. It is then known as nervous aphonia. The loss of voice is due to paralysis affecting the nerve of phonation, namely, the spinal accessory. The affection may be limited to the voluntary movements of the laryngeal muscles, the reflex movements involved in respiration being unaffected.

Functional aphonia is met with not infrequently in women, and is often, but not always, associated with phenomena embraced under the name hysteria. As a purely neurotic affection, that is, not dependent on any lesion of the nervous system, it is extremely rare in the other sex. An obvious distinction is between loss of voice and loss of speech, or aphasia. Aphonia may occur from pressure on the recurrent laryngeal nerve by an aneurismal or other tumor, and the loss of voice should direct attention to this as a possible or probable cause.

The diagnosis of nervous aphonia may be made by attention to the character of the whispered voice; the patient speaks in a pure, soft whisper, without effort. On the contrary, if the aphonia be due to laryngitis, the whisper is stridulous or husky and labored. Moreover, in aphonia due to laryngitis there is more or less cough and expectoration, symptoms generally absent in nervous aphonia. As the question is usually to decide between nervous aphonia and chronic laryngitis, and as the latter affection is generally associated with pulmonary phthisis, the absence of the symptoms and signs of the latter disease will serve to confirm the diagnosis. Examination with the laryngoscope will establish the diagnosis by showing that the larynx is free from lesions; and the absence or the incompleteness of movements of the glottis when an effort to speak is made, may be ascertained by inspection.

Inspection with the laryngoscope shows that paralysis of laryngeal muscles may be bilateral or unilateral; and that the different muscles, namely, the adductors and abductors, the tensors and the laxators, may be affected separately. Unilateral paralysis, of course, points to some cause affecting the pneumogastric nerve on one side only, and it is especially suggestive of an aneurismal tumor pressing upon one of the recurrent laryngeal nerves. Dr. Geo. Johnston states that bilateral paralysis may be caused by pressure upon the recurrent laryngeal or the vagus nerve on one side. He attributes the paralysis on the side opposite to that on which the pressure is made to a reflex influence.[1] A case under my observation exemplified the correctness of this statement. A patient at my clinic had nervous aphonia, and the laryngoscope showed bilateral paralysis of the adductors. The existence of an aneurism seated in the descending portion of the arch of the aorta was ascertained.

The localization of paralysis in the different muscles of the larynx, singly or severally, is to be made by laryngoscopic examination. As a rule, in functional aphonia, the adductor muscles are affected. The patient is unable by an effort of the will to approximate the vocal cords sufficiently for phonation. In paralysis of the abductor muscles the voice is more or less affected. This form of paralysis will claim separate notice. For an account of the laryngoscopic appearances, the symptoms, etc., of paralyses affecting the different muscles separately, the reader is referred to works which treat of diseases of the larynx *in extenso*.[2]

If aphonia be purely neurotic, in other words, involving no lesion of the

[1] *Vide* Monthly Abstract of Med. Sciences, published by Henry C. Lea, Feb. 1875.
[2] Cohen, *op. cit.*, treats fully of laryngeal paralyses.

nervous centres, nor pressure on either the par vagum or the recurrent laryngeal nerve, recovery may be expected after a duration of the affection varying much in different cases. The voice is sometimes restored instantaneously and unexpectedly. I have met with cases in which repeated attacks had occurred.

Treatment in these cases should be directed to the general condition; tonic remedies and invigorating hygienic measures are indicated. Moderate counter-irritation may be useful. Electrization of the laryngeal muscles has been found signally useful. Both the induced and the direct current are used with success. The recovery of the voice sometimes follows a single application, or even a single electrical shock; but, in some cases, the treatment, to be successful, must be continued for several weeks. In some of the cases in which electricity at once effects a cure, there is reason to think that the success is due to a moral influence. Dr. Henry K. Oliver has found the following method of manipulation successful in several cases: The wings of the thyroid cartilage, in their posterior and upper part, are to be compressed by the thumb and forefinger, the patient being instructed, at the same time, to make an effort to speak. In his cases a feeble voice sound, after a little time, was produced, and this was followed shortly by the full restoration of the voice. He explains the effect by supposing that the approximation of the vocal cords from the pressure, as it were, "starts the machinery of the vocal apparatus."[1] It may reasonably be conjectured that the efficacy of the method is measurably, at least, dependent on a psychical effect. Other measures often effective are evidently an operation through the mind. Cohen states that he has repeatedly effected a cure by the use of the laryngoscopic mirror, the patient being led to suppose that its introduction was a curative procedure. The late Professor Ware sometimes succeeded by telling patients that they could recover the voice by an energetic act of the will. A violent mental emotion has sometimes produced sudden aphonia, and, aphonia existing, has sometimes occasioned a sudden restoration of the voice. A case has been related to me in which aphonia had existed for several years, and the patient, a woman, was cured by taking a quantity of spirit sufficient to produce inebriation. She was not accustomed to take alcoholics, but the treatment was advised by her physician, who had heard of a cure having been thus effected in another case.

Whenever there is a partial restoration of the voice, complete recovery may be expected by systematic efforts of speech, in the same way as the control of the will over other paralyzed muscles is effected by means of persistent voluntary exercise. Commencing with the vowels most easily spoken, the practice should extend to those more difficult of utterance, then to consonants and words of one syllable, and finally to sentences. After recovery, the exercise of the voice within the limit of fatigue is to be advised.

Aphonia is sometimes feigned. The malingerers are women actuated by a desire to excite sympathy or to become objects of interest. I have met with two cases in which the patients declared their inability even to whisper. One of these patients communicated by signs and by writing; the other by silent articulate movements of the lips. A curious feature in the first of these cases was, that, during a second visit, accompanied by her husband, while I was in conversation with him, she began to speak in a low voice, and took part in the conversation during the remainder of the interview. No comment was made on this sudden recovery of voice either by herself, her husband, or by me. I met her casually some years afterward; there was then no impairment of voice, and she made no reference to her aphonia except to ask if I

[1] *Vide* Am. Journ. of Med. Sciences, April, 1870.

recollected her consulting me. The subsequent history in the other case is unknown. That the inability to speak is in some instances a self-delusion, is probable. This may have been the explanation in the cases just noticed.

Paralysis affecting the abductor muscles has important distinctive features when contrasted with the paralysis of the adductors. The effect of bilateral paralysis of the abductors is the approximation of the vocal cords, giving rise to more or less obstruction of respiration. The obstruction is manifest especially in inspiration. The condition is analogous to that after the physiological experiment of dividing both recurrent laryngeal nerves. The vibration of the cords with the current of inspired air causes stridor. There is dysphonia, but not complete loss of voice. Dyspnœa exists in proportion to the obstruction. There is danger of death from suffocation, especially if, as may happen, spasm of the adductors be added to the paralysis of the abductors.

In view of the indication for prompt treatment whenever the obstruction is sufficient to involve danger, the diagnosis is extremely important. The laryngoscope renders it positive, and, it cannot be made so otherwise than by inspection of the larynx. In marked cases, the vocal cords are in close proximity, the aperture being reduced to a narrow slit, and no dilatation takes place in the act of inspiration. Without a laryngoscopic examination, the noisy, stridulous, inspiratory sound might suggest either laryngitis or œdema of the glottis.

Tracheotomy is indicated whenever the obstruction involves immediate danger. The indication derives great force from the fact that, with an opening into the trachea, the affection is tolerated indefinitely. Cohen cites a case, within his cognizance, in which a tracheal tube had been worn for more than twelve years, the patient a judge who was able to continue his duties on the bench. He also cites three cases in which life was lost from a refusal to submit to the operation of tracheotomy. If from the occurrence of spasm of the adductors, paroxysms are liable to occur threatening life, there can be no doubt concerning the propriety of tracheotomy as a prophylactic measure, provided the patients are not under instant observation.

Cases in which spasm of the adductors is not an element, may not require surgical interference. A case came under my observation at my college clinic, in which there was a certain amount of dyspnœa, but not enough to threaten life. The patient was sent to Bellevue Hospital, and preparations were made to perform tracheotomy at a moment's notice. Recovery took place without the operation, the treatment consisting chiefly of quietude and assafœtida. Dr. Geo. M. Lefferts has reported two cases of recovery, without tracheotomy, under the use of the iodide of potassium, the patients having had syphilis.[1]

The prognosis, as regards recovery from the paralysis, will depend on the causative conditions. If the paralysis depend on lesions, either centric or peripheral, which are permanent, recovery is not to be expected. Danger of death from obstruction is permanently averted by a tracheal opening. If, however, the paralysis be functional, or if it depend on syphilitic changes, as in the cases reported by Lefferts, the prognosis, as regards recovery, is favorable.

If the paralysis be unilateral and remain so, there is little or no danger from obstruction. The voice is weak and stridulous, simulating chronic laryngitis. In a patient forty years of age, aneurism should always be suspected, and should be sought for, especially in the site of the descending portion of the cord; but the paralysis may depend on other causes, either centric or

[1] New York Med. Journal, Dec. 1878.

peripheral, generally the latter, which affect the recurrent laryngeal or the pneumogastric nerve on one side.

Bilateral paralysis of the abductor muscles is extremely rare. The number of reported cases is small; but it is probable that the pathological character of the affection was not infrequently overlooked prior to the date of laryngoscopy.

Morbid Growths.

The most common tumor within the larynx is papilloma. It takes its origin by preference from that portion of the laryngeal mucous membrane which is covered with flat epithelium. It may have a broad base, or may be connected with the mucous membrane by a distinct pedicle. It consists essentially of hypertrophied and newly-formed papillæ covered with flat epithelium. Small papillomatous growths are not infrequent attendants upon tuberculous and syphilitic laryngeal ulcers and chronic laryngitis. Papillomatous growths, however, may occur without inflammation. Other important forms of new growths are the laryngeal polypi, which may be fibrous, myxomatous, or glandular. Fibroma, myxoma, and adenoma do not, however, necessarily assume a polypoid form in the larynx. Carcinoma of the larynx, when primary, is usually of the flat-celled variety, and takes its origin from that portion of the larynx lined with squamous epithelium, especially from the true vocal cords. Cancer seated primarily in the larynx is rare; the disease, in the cases in which this part becomes affected by it, generally originating in the œsophagus or in the neck exterior to the larynx. Syphilitic and tuberculous new formations have already been referred to. A detailed consideration of these and other rarer forms of laryngeal tumors must be sought in works treating especially of diseases of the throat.

Morbid growths occasion inconvenience, suffering, and death, by producing obstruction. Surgical interference becomes necessary when the obstruction is sufficient to endanger life. A tube may be worn in the trachea for an indefinite period. In a case in which a permanent artificial opening becomes necessary, it may be a question whether a large fistulous orifice might not be established, rendering the tracheal tube unnecessary. As bearing on this question, the following case is of interest: A patient, aged about forty, admitted into one of my wards in Bellevue Hospital, suffering from the effects of a debauch, had a fistulous orifice in the anterior portion of the trachea large enough to admit the end of the forefinger. This fistula followed a wound received in a fracas, and had existed for seventeen years. It occasioned little or no inconvenience in respiration. There were no symptoms of inflammation or irritation of the trachea or bronchial tubes, and he was entirely free from pulmonary disease; the only inconvenience which it occasioned was in speaking. In order to direct a current of air through the glottis sufficient for the production of the voice, he was accustomed to approximate the chin to the sternum, and in this way he was able to close the fistula.

The laryngoscope has proved to be of great practical value in determining the existence, situation, size, and character of morbid growths within the larynx, and in facilitating surgical operations for their removal through the laryngeal aperture. Cohen states that prior to laryngoscopy probably not more than seventy cases of morbid growths within the larynx were to be found in medical literature, whereas within the last twenty years thousands of such cases have been reported.

SECTION SECOND.

DISEASES AFFECTING THE CIRCULATORY SYSTEM.

CHAPTER I.

PERICARDITIS.

Introductory Remarks. Pericarditis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Chronic Pericarditis. Pneumo-Pericarditis.

DISEASES affecting the circulatory system are seated either in the blood-vessels or in the central organ of the circulation—the heart. There is a group of affections existing independent of the organs of the circulatory system and involving certain morbid changes of the blood. The affections belonging in this group are simple or benign anæmia, chlorosis, leucocythæmia, pseudo-leucocythæmia, lymphatic anæmia or Hodgkin's disease, pernicious anæmia, and to these may be added Addison's disease. These affections proceed from defect or disturbance referable to the blood-producing organs. They will be considered in a separate section (Section III.), under the heading Diseases Affecting the Hæmatopoietic System. Morbid conditions of the blood, not recognized as individual affections, being common to different diseases, are considered in Part First of this work. Diseases of the vessels, entering, as they do, much more largely into maladies which belong to the surgeon than into those which fall within the province of the physician, are fully considered by surgical writers. Of the diseases of the arteries, aneurisms situated within the chest and abdomen will alone claim attention in this treatise. Thoracic aneurisms will be noticed in this section; those situated within the abdomen will be referred to in connection with abdominal tumors, in Section IV. Inflammation of the veins (phlebitis) has been referred to in connection with pyæmia. This section will be devoted chiefly to diseases affecting the heart.

The diseases of the heart are conveniently arranged in the following groups: 1. Inflammatory affections. 2. Structural lesions. 3. Functional disorder. Inflammation affecting the heart gives rise to different diseases according to the structure in which it is seated. Inflammation of the serous membrane investing the heart (the pericardium) gives rise to the disease called *pericarditis*. Inflammation of the membrane lining the cavities of the heart (the endocardium) is another disease, called *endocarditis*. Inflammation of the substance of the heart (the myocardium) is distinguished as *myocarditis*. These three inflammatory diseases claim separate consideration.

Acute Pericarditis.

Pericarditis occurs as an acute and as a chronic affection. Acute pericarditis will be now considered, and, afterward, the chronic form of the disease.

Anatomical Characters.—Acute pericarditis may be either diffuse or circumscribed. When circumscribed, the inflammatory products are usually deposited at the base of the heart, near the origin of the great vessels. Diffuse pericarditis is the usual form. The morbid appearances resulting from acute inflammation in this situation are essentially the same as in inflammation of other serous membranes, for example, the pleura. The serous membrane is at first reddened in consequence of congestion and small ecchymoses. The inflammatory exudation consists of fibrin, serum, pus-cells, and red blood-corpuscles. In the majority of cases it is sero-fibrinous, the pus-cells not being sufficient in number to render opaque the fluid part of the exudation. The exudation may consist almost wholly of fibrin, with very little serum. This has been called dry pericarditis. Under exceptional circumstances the red blood-corpuscles are present so abundantly as to give to the serum a reddish or brownish coloration. This constitutes hemorrhagic pericarditis. It occurs especially in connection with tuberculosis or cancer of the pericardium, and, also, as a complication of scorbutus. In very rare instances the exudation is purulent. This may occur in pyæmia, and in consequence of the extension of a purulent inflammation in the neighborhood, as in cases of suppurative pleuritis, hepatic abscess, etc. In acute diffuse pericarditis the fibrin is deposited in the form of a layer, or a series of layers, on the visceral and on the parietal surface of the membrane. It is a peculiarity of this fibrinous pseudo-membrane, that its free surface has a rough, shaggy appearance, due to the projection of numerous filaments and villous processes (cor villosum—hairy heart). This peculiar disposition is attributable to the constant churning action of the heart.

The quantity of liquid effusion in different cases of pericarditis varies greatly, amounting, in some cases, to a few ounces only, and, in other cases, to a pint or more. It is usually of a yellowish color, and contains flocculi of fibrin. Wandering cells or pus-cells are present in the fibrinous layer and in the serum, also in varying numbers in the tissue of the serous membrane itself. Whether these have any other origin than emigration from the blood is still a matter of dispute.

If recovery take place, the serum is absorbed, the fibrin undergoes a molecular disintegration and is absorbed. At the same time new connective tissue, in the form of adhesions, is developed. The process of their formation is the same as in pleurisy (page 125). The pericardial sac may be completely obliterated by the firm adhesion of its two layers, or it may be partially obliterated. The adhesions may also develop in the form of threads and bands stretching between the pericardial surfaces.

Purulent pericarditis runs a less favorable course. Several pints of pus may accumulate in the pericardial sac. It sometimes happens that the parietal layer of the pericardium ulcerates, and the pus may even escape externally by a fistulous opening. It is possible for only small accumulations of pus to be absorbed.

The muscular substance of the heart suffers more or less in its nutrition in all cases of pericarditis. The most frequent change is parenchymatous and fatty degeneration of the muscular fibres situated just beneath the pericardium. The fibrous thickening of the visceral pericardial layer, which follows pericarditis, is sometimes accompanied by the growth of fibrous tissue into the subjacent muscular substance, and a consequent atrophy of the muscular fibres in this situation.

The most convenient mode of dividing simple acute diffuse pericarditis into stages is the same as that adopted in pleuritis. The first stage extends to the time when liquid effusion takes place to an extent sufficient to be appreciated by the physical signs. The second stage, or the stage of effusion, continues until

the liquid is absorbed. The third stage extends from the absorption of the liquid to the recovery, and this is, generally, the stage of convalescence.

Clinical History.—The symptoms are almost invariably made up, to a greater or less extent, of those arising from co-existing affections, for, in the great majority of cases, the disease is associated with either articular rheumatism, Bright's disease of the kidneys, or pleuritis with or without lobar pneumonitis. Under these circumstances, it is not always easy to determine to what extent certain symptomatic phenomena are due to the cardiac disease. As a rule, the development of the inflammation is attended with more or less pain which, in some cases, is acute and lancinating, like the pain in pleuritis, and increased by forced breathing, so that the disease has not infrequently been supposed to be inflammation of the pleura. The intensity of the pain varies much in different cases; it is not always a prominent symptom, and it is sometimes slight or wanting. The pain may be increased by acts of deglutition, by eructations, and it sometimes is analogous to that in angina pectoris. The facies is that of suffering and anxiety. A dry, irritable, suppressed cough is generally present. Tenderness over the præcordia is more or less marked, and pressure in the epigastrium upward in a direction toward the heart, sometimes occasions acute pain. The pain produced by a deep inspiration may cause the patient to shorten this act, and, hence, by way of compensation, the number of respirations per minute is increased. The *alæ nasi* may dilate in inspiration. Patients sometimes manifest suffering from an indefinite sense of distress, without acute, localized pain, and, in women, hysterical phenomena may be associated with the development of the disease. The action of the heart is increased, amounting, sometimes, to palpitation. The pulse is more or less accelerated, quick, and vibratory. Pyrexia and its concomitants, namely, anorexia, debility, etc., are present. These are symptoms belonging to the first stage.

The duration of the first stage is usually short. An appreciable amount of effusion may take place in a few hours, and it is rarely delayed beyond one or two days. The acuteness of the local symptoms, namely, pain and soreness, then diminishes, and, if the amount of liquid effused be sufficient to fill or distend the pericardial sac, symptoms are added which proceed from the pressure of the liquid upon the heart. These symptoms are, a sense of oppression referable to the præcordia; a tendency to syncope on exertion, which leads the patient to refrain as much as possible from movements of the body; feebleness and irregularity of the pulse, with a notable increase on emotional excitement or any muscular effort; dyspnœa, sometimes amounting to orthopnœa, if the accumulation of liquid be large and rapid; feebleness of the voice or even aphonia, and dysphagia, in some cases, produced by pressure of the distended sac on the recurrent laryngeal nerves and on the œsophagus. Cyanosis and turgescence of the cervical veins are sometimes marked, due, probably, to pressure on the auricles and the venæ cavæ. Venous pulse on the neck is sometimes observed. Vomiting is an occasional symptom. Singultus may be produced by pressure on the phrenic or branches of the pneumogastric nerve. Some cases are characterized by remarkable disturbance of the nervous system. Mental aberration, consisting in obstinate taciturnity and indifference, alternating with paroxysms of maniacal excitement under the influence of delusions which excite terror, is occasionally observed. Coma, chorea, and tetanic convulsions have been known to occur. These symptoms are apt to mask the cardiac disease, and lead the practitioner to suspect disease of the brain. Autopsical examinations show that, in these cases, neither inflammation nor any appreciable lesion of the nervous system exists, and, hence, the phenomena are to be referred to functional disturbance of the nervous system.

The severity of the disease, as denoted by the symptoms, corresponds to the intensity of the inflammation and the amount of effusion. If the inflammation be slight or moderate and the quantity of effused liquid small, the disease may run its course without any symptoms denoting gravity, and the symptoms may not even point to the existence of any affection within the chest. In other cases it is one of the most distressing and formidable of diseases. The symptoms due to compression, of course, diminish as the liquid is absorbed. The absorption sometimes goes on very rapidly, and, in this respect, different cases present great variation. If, instead of being absorbed, the liquid continue to accumulate, and life be not rapidly destroyed, the pericardial sac may become greatly dilated, and the affection become chronic. The rapidity and completeness of recovery after absorption will depend on the amount of inflammatory exudation. This may be too abundant to be absorbed, and the disease may end fatally after continuing for a greater or less period in a chronic form. In cases which go on favorably toward recovery, the action of the heart is feeble and easily excited during the stage of convalescence.

Pathological Character.—Acute pericarditis does not differ essentially in character from other serous inflammations. The same series of processes which take place in the serous inflammation considered in the preceding section (pleuritis), occur in this inflammation, namely, fibrinous exudation and liquid effusion, agglutination followed by permanent adhesion of the free surfaces of the membrane, and sometimes the formation of pus. Suppurative pericarditis, however, occurs in a much smaller proportion of cases than suppurative pleuritis or empyema. As in cases of pleuritis and other serous inflammations, so in different cases of pericarditis, both the actual and relative amount of fibrin and serum differ greatly. In some cases, the quantity of fibrin is small and the effusion of liquid abundant; in other cases, the fibrin is abundant with but little liquid, and, again, in other cases, both fibrin and liquid are either abundant or small. Judging from the number of cases which I have seen, *dry* pericarditis, that is, the presence of fibrin without serous effusion, is not extremely rare.

Causation.—Acute pericarditis may be produced traumatically by perforating wounds of the chest, or contusions. In one of the cases which I have observed, it was produced by a wound inflicted by a one-tined fork. Walshe refers to a case in which the pericardial sac was perforated in the juggler's trick of swallowing a sword, and fatal pericarditis induced. In the Museum of Bellevue Hospital is a remarkable specimen, in which a set of false teeth is contained within the pericardial sac. The teeth were swallowed during alcoholic coma, and, lodging in the lower part of the œsophagus, produced ulceration through this tube and into the pericardium, giving rise to fatal pericarditis.

Exclusive of its traumatic origin, the disease is almost always secondary, and it is developed in the course of acute articular rheumatism oftener than in connection with any other affection. Occurring in the course of rheumatism, it is distinguished as rheumatic pericarditis. It would appear, from statistical data, to occur in cases of acute rheumatism in a proportion of about one to six. Sibson, out of 326 recorded hospital cases under his care, found evidence of pericarditis in 63.[1] Without having noted sufficient data for analysis, I am sure that this proportion is considerable higher than in my experience. The comparative infrequency of this complication in the cases which

[1] Reynolds's System of Medicine.

have come under my observation, I am disposed to attribute to the prompt and efficient employment of the alkaline treatment, which, for many years, has been in vogue in this country. Generally the development is in the early part of rheumatism, after more or less of the joints have been affected, but occasionally the pericarditis precedes the articular affection. When it follows the affection of the joints, it is not due, as was formerly supposed, to a metastasis of the articular affection, but it proceeds from the same morbid condition which underlies the latter; in other words, both are effects of a common internal cause which has been supposed to be the presence of lactic acid in the blood. Rheumatic pericarditis is generally associated with endocarditis. The latter existed in 54 of the 63 cases analyzed by Sibson.

Next in frequency to its development in the course of rheumatism, it occurs in connection with either acute or chronic disease of the kidneys. It is not very infrequent in cases of chronic Bright's disease; it is a rare concomitant of the renal affection which follows scarlatina, and in other cases of acute diffuse nephritis. It occurs most frequently with the small kidney of chronic Bright's disease. Its causation is imputed to the accumulation of urea in the blood. Sibson's statistics show that it occurs in as many as eight or nine per cent. of all fatal cases of Bright's disease.

Pyæmia, scorbutus, the continued and eruptive fevers, erysipelas, and influenza, are other affections in connection with which this disease has been observed to occur, the pathological relation, probably, being the same as when it occurs in connection with rheumatism and renal affections, namely, a common causative condition pertaining to the blood. It is a tolerably frequent concomitant of pleuritis and of pneumonitis, affecting either the right or left lung—oftener the latter. And in this connection, it is generally attributed to an extension of the inflammation from the pleura to the pericardium in consequence of the proximity of these membranes. But here, too, it is perhaps more rational to refer the pleural and pericardial inflammation to a common internal causative condition, than to suppose the latter to be dependent on the former.

Idiopathic, spontaneous pericarditis is one of the rarest of diseases. I have, however, met with a few examples, or, at all events, cases in which a careful examination failed to discover any pre-existing or co-existing disease, nor was any other affection developed so long as the patients remained under observation, the period extending only to the time when they had recovered sufficiently to leave the hospital. The extreme infrequency of such cases renders it extremely probable that, whenever pericarditis exists, some one of the affections just named will be found associated with it.

Diagnosis.—The events belonging to the clinical history of acute pericarditis are not sufficiently diagnostic for the disease to be discriminated by the symptoms alone, from pleuritis, pneumonitis, or pleurodynia. Its co-existence with the two former of these affections could not be ascertained, and its existence would surely be overlooked in the cases in which the symptoms are but little marked. The diagnosis must rest on physical signs. The presence of inflammatory exudation gives rise to an adventitious sound or murmur, caused by the rubbing together of the pericardial surfaces in the movements of the heart. This sign is proof of the existence of pericarditis, and, as the exudation takes place usually within a few hours after the commencement of inflammation, the sign becomes available for diagnosis at an early period of the disease. The sign is called the *pericardial* or *cardiac friction murmur*, or sometimes, in contradistinction from the murmur produced by blood-currents within the heart, an *exocardial murmur*.

The friction murmur is to be distinguished from the murmur produced

within the heart, called *endocardial* or *bellows murmur*, by attention to the following points: It is generally double, that is, consisting of two adventitious sounds for each beat of the heart, one produced by the systolic and the other by the diastolic cardiac movements. The character of the murmur denotes friction; that is, it is rubbing, grazing, or grating, and, at a later period in the disease, it may be creaking, like the sound of new leather. It is limited to the præcordia, not propagated beyond the borders of the heart, and it may be limited to a portion of the præcordial space. As regards its intensity, it differs much in different cases, and it is apt to vary in the same case during an examination, the variations dependent on the force of the heart's action. It has not the same fixed connection with the normal heart-sounds as the endocardial murmurs; in other words, it does not observe the same regularity in rhythm as the latter. This is a striking point of distinction. It is intensified and sometimes changed in character by firm pressure with the stethoscope. In connection with a rough friction murmur, fremitus is sometimes felt by the hand applied to the præcordia.

A friction murmur, if ever wanting in the first stage of pericarditis, is present so generally that we are warranted in basing an exclusion of the disease on its absence, provided sufficient time has elapsed for inflammatory exudation, and limiting the question of diagnosis to the first stage. The murmur is almost pathognomonic, taken in connection with the symptoms and history; yet there is one source of fallacy, namely, the production of an intra-pleural friction murmur by the movements of the heart in cases of pleuritis. A friction murmur accompanying the systolic and diastolic movements of the heart, continuing while the patient's breathing is voluntarily suspended, may be thus produced irrespective of pericarditis. I have met with several examples, the absence of pericarditis, notwithstanding a well-marked murmur with cardiac rhythm, having been determined by examination after death. This is called a *cardiac pleural friction murmur*. It is to be suspected, if pleuritis be known to exist, with or without pneumonitis, when the murmur is limited to the border of the heart, the intensity of the murmur varying much more than the ordinary cardiac murmur during the periods of examination, it being heard, in some cases, only at the end of inspiration, and generally affected more or less by the respiratory movements.

In the second stage, the occurrence of liquid effusion and its amount are determined by percussion. Abnormal dulness or flatness exists over an increased area in the præcordial region. The pericardial sac, if filled with liquid, forms a pyriform tumor, the boundaries of which are readily defined by percussion. The base is situated below the level of the apex-beat in health; the left border is without the left nipple, and the right border between the right margin of the sternum and the right nipple; the apex is near the sternal notch. The situation, size, and shape of the area of dulness or flatness point to pericardial effusion. If the pericardial sac be partially filled with liquid, the area of dulness in the præcordia is abnormally widened at and below the apex of the heart, the widening extending more or less upward in proportion to the quantity of effusion. Vocal resonance is diminished or lost within the area of dulness or flatness, and also vocal fremitus. If the sac be distended with liquid, the præcordia may be abnormally prominent and the intercostal depressions abolished, as in pleuritis, within this region. Mensuration will show the increased size of the præcordia. The extent of dulness or flatness at different periods of the disease, will show, on the one hand, progressive increase, or, on the other hand, diminution of the quantity of liquid, and at length its complete removal. Dr. J. M. Roteh has called attention to the fact that the pericardial sac, when filled, gives rise to flatness on percus-

sion in the fifth intercostal space on the right side—a fact which I have clinically verified.

The friction murmur either diminishes or disappears after considerable effusion of liquid has taken place. Not infrequently it continues, although the pericardial sac may be filled with liquid and even much dilated. Under these circumstances, it is sometimes heard when the patient is raised to the sitting posture, and may disappear when the patient lies on the back. If it have disappeared or been diminished during the stage of effusion, it returns, with increased intensity, after the absorption of the liquid; and it then persists until agglutination of the pericardial surfaces takes place. Occasionally it continues during convalescence and after apparent recovery.

The apex-beat of the heart is weakened and may be suppressed by the presence of liquid. If the accumulation of liquid be considerable, the situation of the beat is altered; it is raised to the fourth intercostal space and carried to the left as far as, or even beyond, the line of the nipple. The sounds of the heart are rendered feeble and distant by the presence of liquid, especially the first sound, and this becomes short and valvular like the second sound.

By means of these signs, the diagnosis of pericarditis is generally made without difficulty. Bearing in mind the frequency of its occurrence in articular rheumatism, daily examinations of the chest in cases of that disease with reference to this complication should not be omitted. The fact that it occurs in cases of Bright's disease should also be borne in mind; in fact, it is a good rule, in examining a patient with any disease, not to omit an exploration of the præcordia. Developed in connection with pleuritis or pneumonitis, it is apt to be overlooked, and the diagnosis involves more difficulty than when it occurs in other pathological connections. The determination of pericardial effusion, if a large effusion also exist in the left pleural sac, is not always easy, and the chief reliance in such a case must be on the presence of a friction murmur which is produced, not without, but within the pericardial sac. I have reported a case in which the heart was enveloped in either a carcinomatous or sarcomatous growth, completely filling and distending the pericardial sac without altering its form.[1] In this unique case the signs were those of pericardial effusion, and this was the diagnosis. It is difficult to see how pericardial effusion could be excluded in such a case, except by means of an exploratory puncture, which might have been resorted to without harm.

In a case under my observation the pericardium became agglutinated over the left half of the heart, and the right half of the sac was filled with effused liquid. Such a case, if not observed from the commencement, offers a puzzling problem in diagnosis.

The occurrence of delirium, coma, etc., in some cases of pericarditis, masks the symptoms pointing to the latter. An examination for the signs of pericarditis should not be omitted in cases presenting notable disturbance of the nervous system.

Prognosis.—Acute pericarditis is in some cases a very dangerous disease, but in other cases comparatively mild. The gravity depends much on the intensity of the inflammation, the amount of inflammatory exudation, and more especially the quantity of liquid effusion together with the rapidity with which it takes place. A large quantity of liquid, rapidly effused, may lead quickly to a fatal termination. Death, in such cases, is caused by paralysis of the heart from compression, and cases have occurred in which life was destroyed in this way after the lapse of a few hours only from the time of the attack. Generally, however, the duration of the disease, in fatal cases, is

[1] *Vide* Treatise on Diseases of the Heart, 2d edition.

from one to two weeks, and death takes place by slow asthenia. In such cases, the immediate cause of death is either the prolonged compression of the heart by liquid, or weakening of the heart's action as a direct effect of the inflammation on the muscular fibres, or both causes combined. Sudden death, by syncope, is liable to be produced by muscular exertion, especially if there be much liquid effusion. A patient under my observation, affected with mild pericarditis, died instantly on getting out of bed to go to stool.

But the fatality in cases of acute pericarditis is often due, not so much to the disease *per se*, as to co-existing affections. In fact, exclusive of the accidents just referred to, the disease tends to recovery. The danger varies greatly with its different pathological connections. Rheumatic pericarditis, not associated with pleuritis or pneumonitis, is rarely fatal. On the other hand, pericarditis developed in the course of Bright's disease proves fatal in a very large proportion of cases. This difference is explained by the ability of the system to sustain any important intercurrent affection being widely different in these two diseases. Cases in which the pericarditis occurs as a complication of pleuritis or pneumonitis show a large fatality. Traumatic cases generally end in recovery, provided the heart be not injured. Occurring as an idiopathic affection and uncomplicated, the prognosis is favorable.

If the disease do not prove fatal during its acute course, it either ends in recovery or it becomes chronic. Chronic pericarditis will claim separate consideration. In the cases which end in recovery, the usual result is adhesion, by the intervention of newly formed tissue, of the pericardial surfaces over the whole or the greater part of the organ. In a small proportion of cases the adhesion is limited to a few small spaces. Occasionally, patches of either false or true membrane, without adhesion of the two surfaces, are the only permanent effects of the disease. It is doubtful if complete absorption of the inflammatory exudation ever takes place, followed by no adventitious tissue and leaving no trace of the disease.

Treatment.—The widely different circumstances under which acute pericarditis occurs, must, of course, be taken into account in the treatment. The question as to the propriety of bloodletting and other measures heretofore distinguished as antiphlogistic, can only be entertained in the first stage of the disease, and when it is idiopathic, or traumatic, or connected with rheumatism. These measures are undoubtedly inappropriate when it is developed in the progress of Bright's disease, or when it is secondary to pleuritis or pneumonitis. In general terms, the propriety of these measures admits of consideration only when the pericarditis is either primary, or secondary to affections which do not in themselves impair considerably the ability of the system to sustain an additional disease. When not associated with other diseases which are in themselves dangerous, it is to be borne in mind that pericarditis tends to recovery.

In the cases to which bloodletting must be limited, the general principles which are to govern its employment are the same as in other acute inflammations. These principles have been considered.[1] Some importance, perhaps, belongs to this consideration, namely, by diminishing the mass of blood, the heart is less excited, and its labor diminished. On the other hand, it is to be considered that the danger incident to the disease is mainly from paralysis of the heart or impairment of its muscular power. Giving due weight to these considerations, bloodletting should be employed with great circumspection, even in the few cases in which the symptoms relating to the circu-

[1] *Vide* page 133 *et seq.*

lation, in the first stage of the disease, may appear to indicate it. It is never indicated after considerable effusion has taken place.

Depletion by means of saline purgatives, with restricted diet, is indicated, in the first stage, by the same symptoms as in other acute inflammations. This remark is alike applicable to nauseant and other sedatives. These should be limited to the first stage. They might be pernicious if continued after effusion has occurred, and, hence, the great importance of determining the presence of liquid and its amount, by physical signs.

Shall the system be brought under the influence of mercury in the first stage? This is a question which different writers and practitioners have answered differently, some advocating rapid mercurialization as highly important, others regarding it as needless and hurtful. In the cases in which mercury is by some considered important, and by many admissible, my experience leads me to be satisfied to forego its use.

Opium is of great value in this, as in other acute inflammations. It is indicated by pain and constitutional disturbance, and is to be employed sufficiently to relieve the general and local symptoms. The form of opiate and the mode of administration are to be determined by the circumstances in individual cases.

Locally, mild, revulsive, and soothing applications are useful in the first stage. Sinapisms, a poultice, the water-dressing, or the spongio-piline saturated with a warm anodyne infusion, may be employed. Blisters in this stage should not be employed. Aside from their interference with the daily physical explorations, which are vastly important, they do more harm by adding to the pain and constitutional disturbance, than good by way of revulsion. By German writers cold applied to the præcordia, as in the treatment of acute pleuritis and pneumonitis, is said to be useful. The evidence of its usefulness is the relief of pain, together with diminished frequency of the heart's action.

The indications in the second stage relate, *first*, to the liquid effusion. If the amount of effusion be sufficient to enfeeble the heart by compression, it is highly important to effect the removal of the liquid as speedily as possible. For this end, the præcordia may be painted daily with the tincture of iodine, or small blisters may be applied, removing them as soon as vesication begins, and allowing the blistered surface to dry up rapidly. Hydragogue cathartics and diuretics may be employed, as in pleuritis, taking care not to carry these measures so far as to depress the vital powers and weaken the heart's action. This caution is of great importance, and it suggests a *second* indication which may be present in the second stage, namely, to strengthen the heart's action and support the powers of life by the timely and judicious use of alcoholics, tonics, and nourishment. Keeping in view the fact that the disease, if it end fatally, destroys life by affecting directly the heart's action, the measures just named are indicated with an urgency proportionate to the degree of feebleness of the circulation. All measures which tend directly or indirectly to weaken the circulation or depress the vital powers, are contra-indicated in the second stage. The liability to fatal syncope on exertion is to be borne in mind, and quietude should be rigidly enjoined. Feebleness and irregularity of the pulse in the second, and sometimes in the first, stage, constitute an indication for digitalis which, however, should not be given sufficiently to retard unduly the heart's action.

During the stage of convalescence, precautions against undue excitement of the action of the heart by exercise, mental emotions, over-repletion of the stomach, etc., are more important than during recovery from most other acute inflammations. At the same time, convalescence will be expedited and complete recovery secured, by a nutritious diet, tonic remedies, gentle

gestation out of doors, and other hygienic measures to promote speedy recuperation.

In the treatment of pericarditis developed in the course of either rheumatism or renal disease, it may be important to take into account the supposed presence in the blood of a morbid material upon which the pericardial inflammation depends. The indication derived from this view of the causation is, in general terms, to remove, if possible, the continued operation of the cause, by measures addressed to the morbid conditions of the blood belonging to those affections. This part of the treatment, however, will be more appropriately considered hereafter in connection with rheumatism and renal disease. The importance of measures to prevent the development of pericarditis, in the course of these diseases, will also be then considered.

If the disease end in recovery, without becoming chronic, adhesion of the pericardial surfaces, to a greater or less extent, may be expected to take place. This result was formerly supposed to lead to progressive enlargement of the heart, and therefore pericarditis was regarded as a highly serious disease with reference to its remote effects. This is an error which arose from imputing to pericardial adhesions the consequences of the valvular lesions which often coexist. It may be doubted if adhesions alone tend to produce enlargement, and there is reason to believe that, if not associated with valvular lesions, they may give rise to little inconvenience. The pericardial surfaces are not infrequently found, in autopsical examinations, universally adherent, as a result of ancient pericarditis, without any other evidence of cardiac disease, and when no symptoms referable to the heart had existed during life.

Chronic Pericarditis.

Chronic pericarditis may be subacute from the beginning, or it may follow the acute form of the disease. If acute pericarditis do not end in convalescence after the lapse of from two to three weeks, it becomes a chronic affection. As regards anatomical characters, cases differ. In some cases of chronic pericarditis there is no liquid effusion, but the pericardial surfaces are agglutinated by several layers of fibrinous exudation, which collectively may be half an inch or more in thickness. Under these circumstances the exudation is not absorbed, a low grade of inflammation continues, and the disease often ends fatally after a variable duration.

In other cases liquid effusion remains and progressively accumulates, the pericardial sac becomes more or less dilated, and it is sometimes so much enlarged as to depress the diaphragm and occupy the greater part of the thoracic space. In a case reported by Dr. T. P. Satterwhite, who kindly presented to me the specimen, the liquid removed after death amounted to eight pounds and four ounces.[1] In a case reported by the late Dr. Swett, the quantity of liquid was at least a gallon.

In chronic pericarditis without liquid effusion, pain is rarely prominent. The symptoms are those dependent on feebleness of the circulation, due to the impaired muscular power of the heart, and on constitutional irritation. In the cases in which large effusion exists, the heart is weakened by compression, and the patient suffers from dyspnœa caused by interference with the repiratory function. The dyspnœa may amount to orthopnœa if the accumulation of liquid be large. Pain under these circumstances is rarely a prominent symptom. The symptoms mentioned as due to the pressure of the peri-

[1] Richmond and Louisville Med. Journal, April, 1872.

cardial sac filled with liquid in the second stage of acute pericarditis, may be still more marked when the sac is dilated by effusion in the chronic form of the disease. These symptoms are aphonia from pressure on the recurrent laryngeal nerves; dysphagia from pressure on the œsophagus; cyanosis, turgescence of the cervical veins from pressure on the venæ cavæ and the yielding walls of the auricles; singultus from pressure on the phrenic nerve or branches of the par vagum. Chronic pericarditis with effusion is not to be confounded with pericardial dropsy (hydro-pericardium). The latter occurs in connection with general dropsy, and the accumulation of serum is rarely, if ever, sufficient to dilate the sac. In chronic, as in acute, pericarditis, the liquid is generally sero-fibrinous. In rare instances it is purulent (pyo-pericardium). The effused serum is sometimes colored with blood. This variety of pericarditis, called hemorrhagic, does not claim separate consideration. The term hæmo-pericardium denotes the presence of blood either with or without pericarditis. Without pericarditis, it may be a consequence of wounds which penetrate the pericardial sac, and of the rupture of either the heart or an aneurism. In most, if not all, cases of so-called hemorrhagic pericarditis, the liquid is bloody serum. This occurs especially in pericarditis associated with purpura hæmorrhagica and scorbutus.

The diagnosis, if liquid effusion be not present, must often be inferential, being based mainly on the knowledge of the existence of antecedent acute pericarditis. Creaking friction-murmur exists in some cases, notwithstanding the agglutination of the pericardial surfaces. If friction-murmur be not present, and acute pericarditis be not known to have existed, a positive diagnosis is extremely difficult, if not impossible. The heart is found to be more or less enlarged, but there are no means of determining that the enlargement proceeds from the deposit of fibrin. If liquid effusion be present, the physical signs render the diagnosis easy and positive. Flatness on percussion exists on the anterior surface of the chest, extending on either side of the sternum toward the axillary region in proportion as the pericardial sac is dilated. Obliteration of the intercostal depressions and even bulging may be observed. In a young subject there may be notable projection of the præcordia. Fluctuation in the intercostal spaces is sometimes felt. Laterally, beyond the limit of the flatness on each side, resonance on percussion and the respiratory murmur show the presence of lung. The heart's impulse is suppressed, but a shock communicated by the action of the heart may be felt. A friction-murmur is sometimes heard, even when the quantity of effused liquid is very large. The sounds of the heart are feeble, the first sound being distant, more weakened than the second, and short and valvular like the second sound. These signs render the diagnosis sufficiently clear.

The prognosis in cases of chronic pericarditis is always extremely unfavorable. The disease ends fatally after a duration varying much in different cases.

The indications for treatment are to improve the tone of the system and impart vigor to the heart by tonic remedies, together with nutritious diet and other hygienic measures. The propriety of much counter-irritation is doubtful. Everything which tends, directly or indirectly, to weaken the heart or the vital powers is to be avoided. In this point of view, mercurialization is objectionable. If there be much liquid effusion, diuretic remedies may be tried, and small blisters. Hydragogue cathartics, in these cases, if the patient be feeble, are to be employed with great circumspection. In a case under my observation, elaterium given in small doses and producing but a moderate effect, appeared to hasten the fatal termination. Iodine may be employed as a sorbefacient, externally and internally.

The question as to the propriety of paracentesis relates chiefly to cases of chronic pericarditis. Instances, however, may occur in which, owing to a rapid and large effusion of liquid, this question may arise in connection with the acute disease. If life be in immediate danger from the quantity of liquid, whether the inflammation be acute or not, there can be no room for doubt concerning the propriety of withdrawing the liquid by aspiration. But this question is not restricted to the cases in which it is indicated to avert impending death. May not the rules of practice now generally accepted in cases of pleuritis with effusion and of empyema, be applied to similar conditions in cases of pericarditis? From a rational stand-point, the answer is affirmative. Further clinical experience is requisite to substantiate the correctness of this answer. Following these rules, if a large accumulation of liquid remain undiminished by other measures of treatment, continued for a reasonable period, aspiration should be employed, and the latter is always indicated in suppurative pericarditis.

As preliminary to the operation there is apparently no objection to an exploratory puncture in order to demonstrate the presence of liquid and to ascertain its character. No harm can arise from the puncture with a needle attached to a hypodermic syringe. Even should the heart be punctured therewith, no serious consequences would follow. A needle, however, should not be used in aspiration, except for the objects just stated. A small-sized trocar is unobjectionable. The suction force by means of Davidson's syringe, properly adapted, is preferable to that produced by Dieulafoy's apparatus or its modifications; the former is simpler and more easily managed.

Roberts has tabulated 60 cases of paracentesis of the pericardium. Of these cases the number of recoveries was 24. Of the fatal cases (36), 23 survived the operation for one day or longer, the average duration of life being over 27 days, and the longest duration 160 days.[1] These results strongly sustain the propriety of the operation, especially when it is considered in how large a proportion of cases pericarditis is associated with other grave affections, and that up to the present time the operation has generally been *en dernier ressort.*

The most eligible point for making the puncture is the fifth intercostal space between the sternum and the linea mamallaris, somewhat nearer to the former than to the latter. It is probably an important precaution to withdraw the liquid very slowly. If the liquid be purulent, and, after repeated aspirations, pus continue to reaccumulate, it is very evident that a permanent opening into the pericardial cavity with injections afford the only hope of effecting a cure.

Pneumo-Pericarditis.

This name denotes the presence of air or gas within the pericardial sac in cases of pericarditis. Air or gas may find its way into this situation through a wound of the thoracic walls, or of the œsophagus, and through a fistulous communication between the lungs or the stomach and the pericardial cavity. Air may get access into this cavity through a wound of the chest, and pericarditis not be developed. The condition, then, is expressed by the term *pneumo-pericardium.* I have reported a case exemplifying this statement.[2] It is possible that gas may be generated by decomposition of the products of inflammation within this cavity, but examples must be exceedingly rare.

The presence of air and liquid gives rise to splashing and sometimes metallic sounds with the movements of the heart, which are heard on ausculta-

[1] Paracentesis of the Pericardium, by John B. Roberts, A.M., M.D., etc., 1880.
[2] Vide Practical Treatise on Diseases of the Heart. 2d edition.

tion. Percussion over the præcordia elicits a tympanitic resonance. These cases belong among the curiosities of clinical experience. The treatment of pneumo-pericarditis involves the same principles as the treatment of pericarditis without the presence of air or gas.

Of 28 cases collected by Müller,[1] 9 terminated in recovery. The cases due to traumatism offered the most favorable prognosis. Of 14 such cases 6 recovered.

CHAPTER II.

ENDOCARDITIS. MYOCARDITIS. ANEURISM OF HEART.

Simple Endocarditis — Anatomical Characters — Clinical History — Pathological Character — Causation — Diagnosis — Prognosis — Treatment — Acute Ulcerative Endocarditis — Myocarditis.

INFLAMMATION of the membrane lining the cavities of the heart, or the endocardium, is called endocarditis.

The inner surface of the endocardium is lined by a single layer of flat, polygonal cells, called endothelium. Beneath this, two layers of connective tissue may be distinguished; the one next to the endothelium is extremely rich in elastic fibres, and contains flat and branching cells with some smooth muscle fibres. This elastic layer is connected with the muscular wall of the heart by ordinary fibrillated connective tissue. Capillary bloodvessels pass from the larger vessels in the fibrillated connective tissue into the elastic coat nearly to the endothelium. The valves may be regarded as duplicatures of the endocardium, between the lamellæ of which is a strengthening layer of fibrous tissue derived from the fibrous rings of the ostia. The endocardial lamella is thicker on the auricular surface of the auriculo-ventricular valves than on the ventricular, as the former is more exposed to the force of the blood current. The valves are tolerably rich in capillary bloodvessels extending from the central fibrous layer into the elastic lamellæ beneath the endothelium. The inflammatory lesions of the valves of the heart are most frequently situated, not upon the free edge of the valve, but upon a thickened line a short distance from this edge, known as the line of closure of the valves, and upon the base of the valves.

The inflammations of the endocardium may be divided into simple endocarditis, which may be acute, subacute, or chronic, and acute ulcerative or diphtheritic endocarditis.

Simple Endocarditis.

A sharp line cannot be drawn between the acute and the chronic manifestations of this disease. A subdivision into verrucous or papillary endocarditis in which the anatomical lesions appear as warty excrescences on the endocardium, and sclerotic or contracting endocarditis in which the valves become thickened and shrunken, has been made, but these two varieties of

[1] Müller. Drei Fälle von Pneumopericardie, Deutsches Archiv für Klinische Medicin, Bd. 24, p. 158, 1879.

lesions are so intimately related to each other, and so frequently combined, that they will be considered under a common heading.

Anatomical Characters.—Endocardial inflammation, in the great majority of cases, is localized on the valves and chordæ tendineæ. It is relatively infrequent on the endocardium lining the cavities of the heart. After birth, it is generally limited to the left side of the heart. In the rare cases of endocarditis of the right side after birth, the left is involved as a rule. Before birth, the reverse holds true. Fœtal endocarditis has been often observed, and in the vast majority of cases it is confined to the right side.

Redness, which plays such an important part in the anatomical appearances of the early stage of acute inflammations in most situations, is not of much importance in endocarditis. A diffuse reddish staining of the endocardium, due to post-mortem imbibition of dissolved blood-coloring matter, must not be mistaken for inflammatory hyperæmia. Redness in this situation is only significant when it is arborescent. Nothing is known as to the existence of inflammatory exudation upon the free surface of the endocardium. The essential anatomical characteristic of endocarditis, especially in its early manifestations, is the appearance of so-called vegetations upon the endocardium. These vegetations may be minute and in great number, giving only a roughened appearance to the affected endocardium, or they may attain to the size of a pea or even larger. They are of all shapes, and may be connected with the tissue of the endocardium by a broad base or by a narrow pedicle. They cannot be removed from the endocardium without leaving a loss of substance. This fact, together with their microscopical examination, shows that they are outgrowths from the tissue of the endocardium, and not merely fibrinous deposits from the blood as was once supposed. They are formed by a nodular accumulation of young cells, probably emigrated white blood-corpuscles, in the upper connective-tissue layer of the endocardium. They constitute a kind of granulation-tissue over which the endothelium has disappeared. A more diffuse infiltration with leucocytes, especially around the vegetations, is also met with in the endocardium. Upon the roughened surface of the vegetations white thrombi are deposited from the blood. These thrombi, which may be of considerable thickness, are formed chiefly of white blood-corpuscles and fibrin (page 29). The vegetations, with their caps of fibrin, are favorable points for the formation of emboli which may consist either of broken-off thrombi or of fragments of the vegetations. Less frequently than in acute ulcerative endocarditis, loss of substance of the endocardium may occur from breaking off of the vegetations or by softening and fatty disintegration of the surrounding infiltrated endocardial tissue. Thus, there may result perforation of the valves, or, on the other hand, valvular aneurism in consequence of bulging of their thinned and softened coats.

In the subacute and chronic forms of endocarditis, the vegetations are firmer in their texture, and do not consist so much of granulation tissue as of fibrillated connective tissue usually rich in cells. These firm vegetations may be developed out of the soft, acute vegetations, or they may have been slow in their growth from the beginning. The valves are also much deformed by the thickening of their substance in consequence of the development of new connective tissue which shrinks and causes retraction of the valves. At the same time, the chordæ tendineæ are often shrunken and thickened. Abnormal adhesions between the edges of the valves or between the valves and the heart-wall are frequently formed. Regressive metamorphoses, in the form of fatty degeneration and of calcification of the vegetations and of the thickened endocardium, are usually observed. These various

changes of acute and chronic endocarditis lead to the development of valvular stenosis and insufficiency.

Clinical History.—Authenticated cases of endocarditis disconnected from other diseases which serve to mask its symptoms to a greater or less extent, are wanting. The clinical history of the disease, therefore, as far as it is at present known, will require but a brief space. Our knowledge of the disease is confined chiefly to the cases in which it occurs in connection with acute articular rheumatism, and in a certain proportion of these cases it is associated with pericarditis. Pain referable to the præcordia is not a constant, and is rarely a prominent symptom. The pain, when present, is dull, not sharp or lancinating like the pain in pericarditis or pleuritis. The patient may complain of an obscure sense of distress in the præcordia, not amounting to pain. The action of the heart is morbidly excited. The organ beats with abnormal quickness and frequency, and its action may be irregular. The action of the heart may be out of proportion to the force of the pulse. The local symptoms, in short, as regards the action of the heart, are those of palpitation. In proportion to the acuteness of the inflammation, doubtless febrile movement is induced, together with the symptoms of constitutional disturbance which accompany fever symptomatic of inflammation in other situations. The local and general symptoms, however, are often not prominent, and, as far as these are concerned, the disease is not infrequently latent. Hence the existence of the disease was unknown prior to the early part of the present century.

Pathological Character.—The morbid changes which belong to simple endocarditis are, in many respects, the same as in serous inflammations. Inflammatory products on the surface of the membrane, if they occur in this situation, are carried by the blood-current into the circulation. The local effects of the endocardial inflammation are warty growths, fibrinous deposits, adhesions, etc., an account of which has been given under the heading Anatomical Characters.

Causation.—Endocarditis, in the great majority of cases, is not a primary disease. There is reason, however, to believe that it occurs as an idiopathic affection not very infrequently, and is overlooked in consequence of its latency as regards cardiac symptoms. This may be inferred from the number of cases in which valvular lesions referable to inflammation are found in persons who have never experienced the disease in the course of which endocarditis is apt to be developed, namely, articular rheumatism. As met with in practice, it is generally incidental to the disease just named. The proportion of cases of rheumatism in which it occurs is not settled. The statistics of different observers show a variation from two-thirds to nine per cent. A reason for this variation is that the existence of the disease has been often assumed on insufficient evidence. The ground for this statement will appear in connection with the consideration of the diagnosis. The analysis by Sibson of 325 cases of acute rheumatism, observed by him, gave 79 cases in which there was no evidence of endocarditis; in 161 cases the evidence of endocarditis was considered as positive; it probably existed in 13 cases, and it was noted as threatened in 63 cases. It is probable that in some cases the evidence was considered as complete on insufficient grounds. This statement will apply to cases in which the only evidence was a tricuspid regurgitant murmur, or an aortic direct murmur, and to cases in which valvular lesions may have existed prior to the rheumatism. The cases of probable and threatened endocarditis cannot be said to have any statistical value. The

frequency of rheumatic endocarditis will doubtless be affected in not a small degree by the treatment adopted in the early period of rheumatism. It suffices to say that endocarditis occurs frequently in cases of rheumatism. Endocarditis, like pericarditis, may perhaps in some cases precede the affection of the joints. It may occur at any time in the course of a rheumatic attack, but it is usually developed in the early or middle period.

When developed in the course of rheumatism, it is not from the transference of the affection of the joints to the endocardial membrane; that is, not by a metastasis, but, like pericarditis developed in the same connection, it is produced by the internal causative condition which gives rise to the articular affection. That this causative condition consists of a morbid material in the blood is probable, and the fact of the endocarditis being generally limited to the left side of the heart, has given rise to the theory that the morbific agent is generated within the blood during its passage through the pulmonary organs. It is argued by Richardson that if the agent in the blood exert its effect upon the endocardium by means of the vessels distributed to the heart, there is no apparent reason why the right side should not be affected as well as the left; but, assuming that the agent in the blood acts by being brought into direct contact with the endocardium, it is intelligible that this agent existing in the blood received into the left cavities from the pulmonary circuit should act upon the membrane lining these cavities, and that it may be eliminated, neutralized, or decomposed before the blood has passed through the systemic circuit and reached the right cavities of the heart. This is the view taken by Richardson, and in its support he found that by injecting lactic acid into the peritoneal cavity, endocarditis was produced not in the left, but in the right cavities of the heart, the acid, as he supposed, being destroyed in these experiments before the blood has passed through the pulmonary circuit and reached the left cavities. These experiments have been adduced in support of the hypothesis that the morbific agent which gives rise to the affections of the heart and joints in rheumatism, is lactic acid produced in the blood during its passage through the lungs. Cases in which endocarditis was considered as attributable to the remedial employment of lactic acid in diabetes and other diseases have been reported by Balthazer Foster and others.

Endocarditis and pericarditis are not infrequently associated in cases of rheumatism, and this compound affection is called *endo-pericarditis*. Rheumatic pericarditis rarely exists without endocarditis. The reverse of this, however, does not hold good; endocarditis is not infrequently developed without pericarditis. In Sibson's cases endocarditis without pericarditis occurred in 107, and endo-pericarditis existed in 54.

Endocarditis, either with or without pericarditis, is developed, in a certain proportion of cases, in the course of Bright's disease. It occurs occasionally in the eruptive and continued fevers, and in cases of pyæmia. It may possibly be produced by contusions of the chest. In these general causative connections it is extremely rare. A single instance only of its occurrence in Bright's disease was observed by Sibson. Its occurrence in chorea is supposed to be frequent. Evidence of its existence was regarded as sufficient in 13 of 34 cases observed by Sibson. The sufficiency of the evidence, however, in all of the 13 cases admits of doubt. This frequency of its occurrence is consistent with the supposed relationship of chorea to rheumatism. Recurring attacks of endocardial inflammation not infrequently take place in connection with existing valvular lesions of the heart.

Diagnosis.—The symptoms in cases of endocarditis are insufficient for a positive diagnosis. The symptoms are even less diagnostic than those which belong to the clinical history of pericarditis, and the disease is oftener com-

pletely latent. The diagnosis of this disease, as well as of pericarditis, must rest on physical evidence. The vegetations and fibrinous deposits give rise to an endocardial murmur, and the diagnosis is to be based on the development of this murmur, taken in connection with the symptoms. As the anatomical changes are especially situated upon the curtains of the mitral valve, at least in cases of rheumatic endocarditis, the murmur is usually of mitral origin. The murmur is of a soft or bellows character. It accompanies the first sound of the heart; that is, it is systolic. It is heard loudest at or near the apex of the heart, and may be limited to this situation. As a rule, if, prior to the endocarditis the patient were free from valvular lesions, the systolic murmur is not propagated far without the left border of the heart. It is probable that the anatomical changes which generally occur during the progress of the endocarditis, rarely involve immediate valvular insufficiency either at the mitral or aortic orifice. Hence, the mitral murmur does not proceed from an actual regurgitant current from the ventricle to the auricle. It is not, then, strictly correct to call it a mitral regurgitant murmur. It is an intra-ventricular murmur, or it may be called a *mitral systolic murmur*, this term not implying the occurrence of regurgitation.

Positive evidence of endocarditis is not afforded by the existence of the murmur just named. A mitral murmur exists often without denoting existing inflammation. It may proceed from valvular lesions which are to be presently considered. To be evidence of existing endocarditis, the murmur must be developed under observation; in other words, one must be satisfied that the murmur which is discovered did not exist on a previous examination. As it is generally in cases of rheumatism that endocarditis occurs, let it be assumed that, on the first examination of a patient affected with rheumatism, a mitral murmur is found. The murmur is not proof of endocarditis, for it is not known that the murmur did not exist prior to the rheumatic attack. The existence of endocarditis is only probable, and the probability of the disease is greater if this be the first attack of rheumatism. But if, on a first examination, no murmur be found, and subsequently, a mitral murmur become developed, it is evidence of endocarditis. The evidence is strengthened, if, at the same time, pain or præcordial distress and excited action of the heart point to the occurrence of a cardiac complication.

Reference has been made, thus far, to a mitral murmur only as evidence of endocarditis. Vegetations and fibrinous deposits at the aortic orifice may occur in this disease, giving rise to an aortic murmur. An aortic direct murmur, and, also, a pulmonic direct murmur, however, are not infrequent in cases of rheumatism without endocarditis, more especially in women, being due to the condition of the blood; in other words, being inorganic murmurs. Hence, a positive diagnosis of endocarditis is not to be based on these murmurs, unless the symptoms, at the same time, denote a cardiac complication, and pericarditis is excluded. Irrespective of cases of rheumatism, it is well known that an aortic murmur with the first sound, *i. e.*, systolic, is common as an inorganic murmur, and, alone, is never proof of endocarditis. Insufficiency of the aortic valve, as an immediate effect of endocarditis, must be rare. Sibson, however, gives some instances in which this effect was shown by the occurrence of an aortic regurgitant murmur developed during the rheumatism, and afterward disappearing.

In view of the fact that in the great majority of the cases of endocarditis it is a complication of articular rheumatism, not only do we seek for the evidence of its development in the course of the latter disease, but the existence of articular rheumatism renders the diagnosis more complete than if this disease did not exist.

Endocardial murmurs produced by endocarditis are generally permanent,

but I have repeatedly known a mitral murmur to disappear after recovery from rheumatism. I have known an aortic and a mitral murmur to continue for several years after recovery, and at length disappear entirely. In cases of endo-pericarditis, the endocardial exists with an exocardial or friction murmur. In general, the two murmurs may be readily distinguished, and each referred to its source.

Prognosis.—In the great majority of cases, simple endocarditis involves no immediate danger. The danger is, for the most part, remote, relating to the valvular lesions which are apt to follow. (*Vide* Chapter III.) The persistence of inflammation in a chronic form is not determinable. The continuance of an endocardial murmur is not proof that inflammation persists; roughening of the membrane from either vegetations or thrombi which remain, will suffice to produce murmur. The chief source of important morbid effects, exclusive of valvular lesions, is embolism. Vegetations, or masses of fibrin of greater or less size, are liable to be detached, and, forming emboli, occasion obstruction (infarction) of arteries in different organs. Passing, of course, into the systemic circulation, they are especially apt to become lodged in the spleen and in the kidney, where they give rise to characteristic lesions. They may be carried into the central artery of the retina, and give rise to impairment of vision. Again, cerebral embolism may occur, and cases have occurred in which gangrene of the lower limbs has resulted from embolic obstruction of their distributing arteries. In the latter case the arteries are generally atheromatous, or the circulation much enfeebled. For a general account of embolism, the reader is referred to the first part of this work. (*Vide* page 30, *et seq.*) These are accidents incidental to endocarditis. In general, as occurring in the pathological connection in which it usually occurs, namely, in the course of acute articular rheumatism, and disconnected from pericarditis, endocarditis involves no immediate danger, and gives rise to no symptoms denoting gravity of disease; it is frequently latent, and is an important complication chiefly because it may be the foundation for valvular lesions which, after the lapse of many months, or it may be many years, occasion serious consequences.

Treatment.—Simple endocarditis being confined, generally, to the left side of the heart, and limited chiefly to the valvular portion of the endocardium, does not occasion great constitutional disturbance. Præcordial pain and disturbed action of the heart indicate anodyne remedies and soothing applications to the chest. Blisters, with reference to these symptoms, are of doubtful propriety. Sinapisms and stimulating liniments will secure all the advantages to be derived from counter-irritation.

Measures addressed to the supposed causative condition of the blood are rationally indicated. Occurring generally in connection with rheumatism, if the local manifestations, this affection of course included, depend on the presence of a morbid material in the blood, it is plainly an object either to neutralize or eliminate this material. The means to be employed for this object will be hereafter considered in connection with the subject of rheumatism; but it may be here stated that the most important measure is the administration of alkaline remedies in doses sufficient to produce and maintain alkalinity of the urine. The importance of this measure, in order to prevent the occurrence of both endocarditis and pericarditis, in cases of rheumatism, will enter into the consideration of the treatment of the latter disease.

The remote evil consequences of endocarditis proceed from thickening, morbid growths, and the deposit of fibrin upon the valvular portion of the endocardium. It is, therefore, undoubtedly desirable to limit and remove

these immediate effects of the inflammation. The condition of hyperinosis is more marked in rheumatism than in any other disease, and, perhaps, increases the tendency to fibrinous deposits. With this view, measures addressed to that condition are rationally indicated. Alkaline remedies, there is reason to believe, lessen the liability to fibrinous deposits. Mercury has been supposed to have this effect. That it possesses this power, however, has been inferred rather than demonstrated, and the correctness of the inference admits of doubt. It may be doubted whether the fibrin deposited upon the membrane is ever absorbed; it either remains or is washed away, gradually or in mass, by the current of blood. The importance of absolute rest during the endocardial inflammation, and for some time afterward, has been enjoined by Sibson, and more especially by Fothergill.[1] The object is to secure a normal minimum of the heart's action, in order to prevent changes in the valves leading to permanent valvular lesions. It is reasonable to suppose that these are promoted by an increased strain upon the valves weakened by existing or recent inflammation; hence, everything is to be avoided which will increase the strain beyond that necessarily involved in the tranquil action of the heart. This precaution embraces avoidance of not only physical exertion, but mental excitement, a stimulating diet, and the use of alcoholics. It is to be added, however, that a good nutrition is to a certain extent protection against these lesions. A diet so reduced as to occasion impoverished blood is injurious.

The practitioner should bear in mind that the persistence of an endocardial murmur is not sufficient ground for persistent medication. The persistence of the murmur is not evidence that the inflammation continues. The medicinal treatment of endocarditis should cease when the local and general symptoms of the disease are no longer present.

Acute Ulcerative Endocarditis.

Among the synonyms for this affection may be mentioned diphtheritic, mycotic or bacteritic, malignant, puerperal, and pyæmic endocarditis. Its recognition as a distinct disease is comparatively recent. Of those who have especially investigated its pathology may be named Virchow, Heiberg, Maier, Eberth, and Köster. The name acute ulcerative endocarditis is perhaps not the best, as simple endocarditis may be attended with the formation of ulcers, but it is the name commonly employed.

Acute ulcerative endocarditis is distinguished by the malignancy of its course. It may be primary, but it is usually secondary to acute infectious diseases, and, in either case, it is accompanied by symptoms of severe blood-poisoning and usually by the development of multiple abscesses.

Anatomical Appearances.—In this disease there are formed upon the endocardium, most frequently of the valves, little reddish or grayish granulations, which are usually closely set in rows or in patches. The granulations may be easily scraped off, leaving a raw surface behind. The substance of the valve, to a greater or less extent, is swollen, softened, and lustreless. Ulcers, usually of small size, are met with on the valves, and present, on their infiltrated borders and base, a reddish-gray, granular deposit. Fibrin and white blood-corpuscles are usually deposited from the blood upon the ulcers and granulations. Valvular aneurisms may be formed by bulging out of the thinned and softened endocardium at the base of the ulcers in consequence of the blood pressure. These aneurisms, when on the mitral valve,

[1] The Heart and its Diseases. By J. Milner Fothergill, M.D., etc. Second edition, 1879.

generally project toward the auricle; when on the aortic valve, toward the ventricle. Of grave import are the perforations and rupture of the valves which may result from the ulcerative process. In a similar way rupture of the chordæ tendineæ may occur. In consequence of rupture of the valves or of the chordæ tendineæ, regurgitation of the blood takes place. Fragments of the valves or portions of the granular or of the thrombotic deposits may be carried into the circulation as emboli.

Microscopical examination reveals, both in the granular deposits and in the substance of the endocardium, colonies of sphæro-bacteria or micrococci (page 96). These have also been found in the capillaries and small arteries of the valves. The first effect of the colonies of micrococci is to cause the cells, for a certain distance around them, to lose their nuclei and to undergo the modification described by Weigert and Cohnheim as coagulation-necrosis (page 52, *et seq.*). Outside of this non-nucleated zone, the white blood-corpuscles migrate and wander into the necrosed tissue. In some cases there are comparatively few pus-cells, in other cases they accumulate in sufficient numbers to form little abscesses and to materially assist in the destructive process. It has been usually held that the micrococci are first deposited out of the blood upon the free surface of the endocardium; it has been recently claimed by Köster,[1] however, that they first appear as emboli in the vessels of the endocardium. Either view involves their preëxistence in the circulating blood. While all pathologists now admit the constancy with which colonies of micrococci are found in acute ulcerative endocarditis, there is not the same agreement as to the part which they play in the causation of the disease.

Among the most frequent complications of acute ulcerative endocarditis are multiple abscesses. It is characteristic of the emboli which are swept off from the endocardium in this disease, that they are infectious, and produce, even when of capillary size, abscesses where they lodge. The emboli of simple endocarditis produce only mechanical effects, being non-infectious or bland emboli. The most frequent situations for the lodgment of emboli from the heart, are the spleen, kidneys, and brain. All of the abscesses in this disease are not necessarily of embolic origin; they may be directly referable to the infectious principle (micrococci?) in the blood. In many cases the abscesses precede the development of the endocarditis. It has not been established that the petechiæ often observed in the skin in this disease are produced by capillary emboli, as has been claimed.

Other organic changes, such as enlargement and softening of the spleen, ecchymoses and parenchymatous degenerations, are common to this affection and many other acute infectious diseases.

Acute ulcerative endocarditis occurs, as a secondary affection, in connection with acute rheumatism, puerperal fever, and pyæmia. In these connections the symptoms referable to the endocardial affection are commingled with those of the associated diseases, and the affection is liable to be overlooked. If endocardial murmurs be ascertained, they may be supposed to denote only simple endocarditis. Well authenticated reported cases of primary ulcerative endocarditis are, as yet, too few to furnish numerical data for a clinical history.

Subjective phenomena referable to the heart are not marked, and are often wanting. The prominent symptoms are constitutional, and attributable to blood-poisoning caused by infective matter contained in the blood. Following an initial chill there is high fever, with notable remissions, the latter

[1] Köster, Die embolische Endocarditis. Virchow's Archiv, Bd. 72, p. 257, 1878.

occurring irregularly, or, sometimes, simulating those of periodical fever. There may be repeated chills; vomiting and diarrhœa are frequent symptoms; jaundice occurs not infrequently; purpuric spots on the skin are not uncommon; prostration is great, and death is preceded by delirium and coma. Local symptoms in other organs than the heart arise from infective emboli. The affection being generally seated in the left side of the heart, emboli are carried to the spleen and kidneys. The spleen becomes enlarged and tender on pressure. Albuminuria may be present with or without renal embolism, and hæmaturia sometimes occurs. In exceptional cases the right side of the heart is the seat of the affection, and then embolic abscesses may be produced in the lungs. The symptomatology, in some cases, is suggestive of typhoid fever, and, in other cases, it accords with that of pyæmia, so that the disease has been considered as presenting two types, denominated typhoid and pyæmic.

Death takes place within a brief period. Dr. John M. Keating has reported a case in which a perforating ulcer led to rupture of the heart, the disease in this case, apparently, being primary.[1]

When the disease is secondary to pyæmia, it is not easy to determine whether the pyæmic symptoms are referable in any measure to the heart. Practically this question is not one of much moment. The symptoms which have been enumerated, occurring in cases of acute rheumatism, and connected with the physical signs of endocarditis, point to this endocardial affection. Further evidence of its existence is afforded by the rapid production of regurgitant lesions of the aortic or the mitral valve, provided it be known that these lesions were not present prior to the occurrence of the attack of rheumatism. The diagnosis, when the disease is primary, can be made with more positiveness. It is to be based on the symptoms and signs of an endocarditis followed by the general and local symptoms which denote pyæmia. Pre-existing valvular lesions of the heart, however, render it difficult to decide as to a recently developed endocarditis, so that, under these circumstances, the diagnosis is not easy.

The pathology involves an inquiry respecting the agency of the parasitic organisms found within the heart in producing the endocardial lesions together with the local changes in other organs and the general phenomena of the disease. This inquiry may be merged into that which relates to the pathology of pyæmia in general. (Part I. page 85.)

It is not known that recovery from acute ulcerative endocarditis ever takes place. With a prognosis based on this fact, all that can be done in the way of treatment, with our present knowledge, is to be guided by symptomatic indications, and to endeavor to obviate the tendency to death.

Myocarditis. Partial Aneurism of Heart.

Inflammation of the muscular structure of the heart is called myocarditis. It occurs in two forms, namely, suppurative myocarditis or abscess of the heart, and chronic interstitial myocarditis. Abscess of the heart is met with in connection with acute ulcerative endocarditis, pyæmia, and, more rarely, in the course of other acute infectious diseases. There may be a single abscess in the myocardium, or multiple abscesses. In cases of pyæmia, large numbers of bacteria are found, especially in the early stages of the abscess. The pus may be discharged into the pericardial sac, giving rise to purulent pericarditis, or into one of the cavities of the heart. In the latter case the blood makes its way into the abscess-cavity, thus leading to the formation of

[1] *Vide* Transactions of the College of Physicians of Philadelphia. Third series, vol. iv., 1879.

acute cardiac aneurism. Rupture of the heart may be a consequence of purulent myocarditis. An abscess in the interventricular septum may lead to perforation and communication between the two ventricles. There is reason to believe that, in rare instances, the abscess may become encapsulated, and the thickened pus remain innocuous. Possibly a small abscess may cicatrize.

Chronic interstitial myocarditis leads to the formation of bands and nodules of fibrous tissue, which replaces the muscular tissue. It is also called indurative or fibrous myocarditis and fibroid degeneration of the heart. It is not uncommon in connection with chronic endocarditis and pericarditis. In such cases there is a direct continuation of the fibroid transformation of the endocardium or of the pericardium into the subjacent muscular structure. The new formed connective tissue grows between the muscular fibres which are thereby compressed and atrophied. In this way the wall of the heart, over a surface of variable extent and to a greater or less depth, becomes transformed into fibrous tissue. This weakened spot in the heart-wall may yield to the blood-pressure, and, bulging out in a sacculated form, make the wall of an aneurismal dilatation. This is the usual method of development of the so-called chronic partial aneurism of the heart. Such aneurisms are most frequently seated near the apex of the left ventricle, more rarely at the base of the ventricle, where they occupy by preference the situation of the pars membranacea septi. They often contain thrombi; they may become partially obliterated by shrinkage of the new fibrous tissue; they may lead to rupture of the heart.

In certain instances bands and masses of fibrous tissue, usually of small size, are found in the substance of the myocardium independent of fibrous thickening of the endocardium or pericardium. The origin of these indurated patches is not well understood. In some instances they may be attributable to infarctions resulting from emboli in the coronary arteries; they may also develop in connection with gummata in the heart-walls.

The most characteristic form of syphilitic disease of the heart is the development of indurative endocarditis and myocarditis in connection with gummata in the heart-wall. It is probable that similar indurative processes may occur in the heart in syphilis independently of gummata. Gummatous myocarditis may also lead to the formation of partial cardiac aneurisms.

Some authors assume the existence of a parenchymatous myocarditis, either general or circumscribed. Most of the changes which have been described as belonging to acute parenchymatous myocarditis, are, in reality, those of albuminous or fatty degeneration of the muscular substance. There is not adequate evidence of the existence of a parenchymatous inflammation of the heart-muscles. Myocarditis, like endocarditis, attacks most frequently, after birth, the left ventricle.

It may be inferred that the myocardium is the seat of lesion of some kind when cardiac symptoms denote something more than functional disorders, and when enlargement, pericarditis, endocarditis, and valvular lesions can be excluded. To differentiate the different myocardial lesions is impossible. To meet symptomatic indications is all that can be done in the way of treatment, were it practicable to recognize during life the foregoing pathological changes.[1]

CHAPTER III.

VALVULAR LESIONS WITH ENLARGEMENT OF THE HEART.

Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment.

HAVING considered, in the two preceding chapters, the inflammatory affections of the heart, the structural lesions of this organ next claim attention. The structural lesions relate, in the first place, to the valves and orifices of the heart. These are known commonly as *valvular lesions*. Other lesions relate to the walls and cavities of the heart. Enlargement of the heart generally proceeds from valvular lesions, and the latter, sooner or later, in the great majority of cases, give rise to enlargement. In considering, therefore, valvular lesions, I shall also consider enlargement as dependent thereon, and afterward notice enlargement occurring without valvular lesions.

Anatomical Characters.—Valvular lesions, in the great majority of cases, are due to chronic endocarditis. When developed after birth, they are nearly always situated in the left side of the heart, that is, at the mitral or the aortic orifice. Tricuspid and pulmonic lesions are comparatively rare in extra-uterine life. Rheumatic endocarditis most frequently attacks the mitral valve. With chronic inflammation of the aortic valve, an atheromatous condition of the neighboring portion of the aorta is usually present, the processes in the valves and in the inner membrane of the aorta being essentially similar. Aortic lesions, therefore, like atheroma, are more frequent in advanced life than in youth. Chronic endocarditis of the aortic valves is often associated with a similar change in the mitral, particularly in its aortic segment. The changes in the endocardium produced by chronic inflammation have already been referred to in treating of endocarditis. The morbid process in the valves may begin either acutely or subacutely, or it may develop slowly and insidiously. The essential change is the formation, in the substance of the valve, of new fibrous tissue of firm consistence, and with a marked tendency to retract. The thickening is usually most marked along the edges of the valves, where frequently warty outgrowths of fibrous tissue are observed. Calcification and fatty degeneration of the new connective tissue are often extensive. The anomalies in the valves resulting from these changes are: 1, thickening and rigidity due to the formation of new connective tissue and the deposit of the salts of lime; 2, shortening in consequence of retraction of the newly formed tissue; 3, adhesion of the valvular segments with each other, or with the heart or vessel-wall; 4, valvular aneurisms and rupture of the valves. Shortening, rigidity, and sometimes rupture of the chordæ tendineæ may co-exist. Deposits of thrombi may be present on the thickened and calcified valves, and serve as a source of emboli. Emboli may also be formed by ruptured fragments of the valves or by breaking off of calcific incrustrations. The thickened valvular segments are sometimes united at their sides to such an extent as to leave only a buttonhole-like slit sufficient

for the admission of the end of the little finger, or, sometimes, in the case of the aortic valves, for the passage only of a crow's quill.

The importance of these various changes lies in the fact that they constitute the vast majority of those structural alterations which interfere with the function of the valves. From a clinical point of view, all the diverse alterations of structure embraced under the name valvular lesions may be arranged, according to their effects upon the circulation, into the following groups: *First*, obstructive lesions, that is, lesions which impede the flow of blood by producing contraction or stenosis of the orifices; *second*, regurgitant lesions, that is, lesions which render the valves incompetent or insufficient, consequently allowing backward or regurgitant currents; *third*, lesions which involve both obstruction and regurgitation; and, *fourth*, lesions which involve neither obstruction nor regurgitation, but give rise to morbid sounds by roughening the surface over which the blood flows. The lesions belonging to the last group are of little or no immediate importance, and, although giving rise to abnormal sounds, known as endocardial or bellows murmurs, they are innocuous. The most frequent form of lesion is that which occasions both obstruction and insufficiency at the same time, one or the other of these effects frequently preponderating. Obstruction unaccompanied by any regurgitation is rare, while regurgitation without obstruction is not infrequent. In certain instances we must recognize the existence of so-called *relative insufficiency* of the valves. This is incident to cases of marked dilatation of the heart-cavities, the ostia becoming so wide that the unchanged valvular segments are incapable of completely closing the dilated orifices. This condition is met with most frequently at the tricuspid orifice in cases of extreme dilatation of the right ventricle as a consequence of mitral disease.

The lesions which involve obstruction or regurgitation lead, primarily, to certain changes in the heart itself, and, secondarily, to alterations in various other organs of the body. These changes in the heart are, at first, of a nature to compensate more or less completely the impairment of function of the valves. The mechanical effects of obstruction or of regurgitation at any of the valvular orifices, when not compensated, are a diminution in the amount of blood supplied to the aorta and general arterial system, and a corresponding over-repletion of the systemic veins. These effects are produced by stenosis and by insufficiency from valvular disease of either the left or of the right side of the heart. The blood pressure in the systemic arteries is therefore lessened, while that in the veins is increased, and the result is retardation of the general circulation. These effects of impaired function of the valves are, at first, more or less completely compensated by increase in the capacity and the strength of certain portions of the heart. Certain cavities dilate and their walls become hypertrophied, so that, notwithstanding the valvular defects, the arteries of the body receive their proper amount of blood. During what may be termed the period of compensation, the hypertrophy bears a harmonious relation to the dilatation; when the compensation becomes disturbed or destroyed, the dilatation exceeds in proportion the hypertrophy. During the stage of compensation, which may last for years, the individual suffers but little inconvenience from the valvular lesions. Sooner or later, in the majority of cases, the compensation is disturbed, and various characteristic symptoms and morbid changes ensue.

In order to understand the changes in the heart, it is well to consider individually the different valvular lesions as to their effects. In cases of insufficiency of the mitral valve, the most frequent of all valvular lesions, during the systole of the left ventricle, a portion of the blood is sent back into the auricle and the aorta receives a proportionately smaller amount of blood. During the diastole, an abnormally large amount of blood flows into the left

ventricle in consequence of the over-accumulation in the left auricle and the pulmonary veins. The left ventricle is thereby over-filled, and, as a consequence, its wall becomes hypertrophied. At the same time, the left auricle becomes dilated and hypertrophied; but the hypertrophy of the thin-walled auricle cannot compensate the over-accumulation of blood. The blood is, therefore, dammed back upon the pulmonary veins, whence the increase of tension is transmitted through the pulmonary vessels to the right ventricle. This becomes over-distended with blood, and, in turn, it becomes hypertrophied. Mitral insufficiency is thus compensated by the hypertrophy of the two ventricles, so that, notwithstanding the regurgitation at the mitral valves, a normal amount of blood is transmitted into the aorta. The muscular coat of the auricles is so thin that they can accomplish but little in the way of compensating valvular lesions. It may be that the compensation for mitral insufficiency is so complete that the patient suffers for a considerable period no inconvenience. When the compensation is destroyed, the dilatation becomes excessive, the right auricle becomes over-distended, and the blood is dammed back upon the general venous system. The effects of this venous congestion of the various organs and parts of the body will be presently described.

In mitral stenosis less blood than normal flows into the left ventricle through the contracted orifice during the diastole. The blood accumulates in the left auricle which dilates and becomes hypertrophied. The blood pressure, as in mitral regurgitation, increases in the pulmonary vessels, and, consequently, the right ventricle becomes overfilled and hypertrophied. Inasmuch as the left auricle and right ventricle are rarely able to completely compensate the obstruction, the left ventricle receives less than the normal amount of blood, and being called upon to do less work, it becomes atrophied. Mitral stenosis unaccompanied by regurgitation and consequent hypertrophy of the left ventricle, however, is rare. It will be observed that while mitral regurgitation is compensated by hypertrophy of both ventricles, mitral stenosis is compensated essentially by hypertrophy of the right ventricle, and is less fully counteracted.

The immediate result of insufficiency of the aortic valves is that, during the diastole, a portion of the blood which had been driven into the aorta by the systole, flows back into the left ventricle. The ventricular cavity is thereby over-filled and its wall becomes hypertrophied, so that, by its increased power of contraction, the excessive amount of blood which accumulates in the left ventricle during the diastole can be forced into the aorta. In this way the arteries can receive their normal quantum of blood notwithstanding the regurgitation. No valvular lesion, as a rule, is more completely compensated than aortic insufficiency. In consequence of the backward flow of blood from the aorta, the left auricle cannot empty itself as readily as usual, and therefore dilates and becomes hypertrophied. The blood is then dammed back upon the lungs, and, as in the previous instances, the right ventricle becomes hypertrophied and dilated. The tension in the right ventricle may be still further increased by simultaneous involvement of the mitral valve in the endocarditic process, or, rarely, by relative insufficiency of the mitral valve.

In aortic stenosis the left ventricle, being unable to completely empty itself, becomes hypertrophied and dilated. The degree of dilatation, however, is usually less than in cases of aortic insufficiency. Dilatation and hypertrophy of the left auricle and of the right side of the heart are produced in the same way as in the valvular lesions already described. The most extensive enlargements of the left ventricle met with, are those consecutive to aortic insufficiency accompanied with moderate stenosis. Aortic lesions

are situated more favorably, as regards completeness of compensation, than mitral, because the former defects are counteracted by hypertrophy of the ventricle immediately behind the valves, while the latter require hypertrophy of the opposite ventricle, to which the increase of tension must be transmitted through the pulmonary vessels. When, however, the compensation of aortic lesions becomes disturbed, in other words, when the left ventricle is no longer able to meet the increased demands upon its strength, the grave symptoms of venous stagnation follow with greater rapidity than after disturbance of the balance in mitral lesions.

After birth, relative insufficiency of the tricuspid valve is more frequent than insufficiency due to chronic endocarditis of the valve. In either case the affection is usually secondary to disease of the left ventricle. As the result of tricuspid regurgitation, less blood than normal is sent to the pulmonary vessels, and therefore the pressure in the pulmonary veins and that in the aorta are abnormally diminished. On the other hand, in consequence of the over-accumulation of blood in the right auricle, the right ventricle is filled under increased pressure. Hypertrophy and dilatation of the right auricle and of the right ventricle ensue in the same way as enlargement of the opposite cavities in mitral regurgitation. In uncomplicated tricuspid regurgitation the left ventricle does not enlarge, because the pressure in the pulmonary veins is not increased, and the aortic tension is not elevated, notwithstanding the regurgitation of blood into the general venous system. Tricuspid regurgitation is therefore imperfectly compensated.

Stenosis of the tricuspid valve, unaccompanied insufficiency, has only been observed as a result of fœtal endocarditis. Uncomplicated tricuspid stenosis belongs among the curiosities of medical experience. It is the most unfavorable of all valvular lesions as regards compensation. It can be only very imperfectly compensated by dilatation and hypertrophy of the right auricle, all of the other cavities of the heart receiving less than the normal amount of blood, and therefore becoming atrophied. Tricuspid stenosis, as a rule, is accompanied by other valvular lesions.

Stenosis and insufficiency of the pulmonic valves are well recognized forms of congenital valvular disease. Still they are very rare. When of fœtal origin, they are often complicated with other anomalies, such as stenosis of the pulmonary artery or of the conus arteriosus, perforation of the septum ventriculorum, and non-closure of the foramen ovale or of the ductus Botalli. When uncomplicated, they are compensated often completely by dilatation and hypertrophy of the right auricle and ventricle. The left side of the heart does not enlarge, but, on the other hand, has been found atrophied. These lesions may be developed in very rare instances as a sequence or concomitant of chronic endocarditis of the left side.

We have now considered the mechanism of the production of the primary changes in the heart following valvular lesions. It has been shown that the different lesions may be compensated to a greater or less extent by hypertrophy and dilatation of certain cavities of the heart. The dilatation is mechanically produced by over-accumulation of blood, the hypertrophy is the result of augmented nutrition of the muscular wall consequent upon the demand for increased activity of the heart. In favorable cases the hypertrophy bears a certain definite relation to the dilatation and to the degree of obstruction or regurgitation, so that the functional defects of the valves are as nearly counteracted as may be. In unfavorable cases, even very early, the dilatation may so predominate over the hypertrophy that the valvular lesion may never be as fully compensated as is possible. This is apt to be the case in persons very much enfeebled, especially when the valvular defects are acutely developed.

In nearly all valvular lesions, either early, or, more frequently, after a

variable period of compensation, the dilatation comes to bear an excessive ratio to the degree of hypertrophy, and the blood is dammed back upon the general venous system. Changes referable to chronic venous congestion or passive congestion of various parts of the body ensue. A knowledge of these changes is necessary to a proper understanding of the symptoms common to uncompensated valvular lesions. They can only be referred to briefly here, as their description belongs to other sections of this work.

The compensation is sometimes disturbed by extension of the morbid processes in the valves, and in many cases it is impaired by fatty degeneration of the hypertrophied muscular surface. Depression of the general vitality of the patient and the occurrence of intercurrent disease likewise enfeeble the heart. In some cases, however, the cause of the failure of the heart is not evident.

In the lungs, as a result of chronic venous congestion, the condition already described as brown or pigment induration is developed (page 185). In this state the pulmonary capillaries are distended and encroach upon the air-cells. Hemorrhagic pulmonary infarctions are frequent, produced by emboli in branches of the pulmonary artery (page 284). These emboli are derived usually from thrombi formed in the right side of the heart. It is not rare in the later stages of valvular disease for thrombi to form, especially in the apices of the ventricles and in the auricular appendices, in consequence of the retardation of the blood-current. Chronic bronchitis usually attends valvular lesions of the left side of the heart. The condition of the heart during the stage of non-compensation is particularly favorable for the production of œdema of the lungs.

In consequence of chronic passive congestion, the condition called nutmeg-liver is developed. The blood being dammed back upon the inferior vena cava and hepatic veins, the central veins of the hepatic lobules become distended, and the lobules present a red centre and light periphery. In the peripheral zone the hepatic cells often contain fat. This swollen state of the liver may be followed by a so-called red atrophy of the organ, a condition to be hereafter described in Section IV.

Chronic congestion of the spleen is evident, after death, from its enlargement, dark color, and firm consistence. The kidneys are enlarged, and, in typical cases, of extremely hard consistence and of a dark red color. This condition was formerly mistaken for chronic interstitial nephritis. The albuminuria of cardiac disease is explained by increase of pressure in the renal veins, and the diminution in the amount of urine excreted, by the diminished tension in the renal arteries. Chronic congestion of the alimentary tract may induce chronic inflammation of the stomach and intestine. Cyanosis and anasarca, with transudation of serum into the various serous sacs of the body, result from the general venous congestion. In consequence of the retardation of the general circulation, the blood may coagulate in the peripheral veins and venous sinuses of the body. Thrombi, so formed, are called marantic (page 28). They form an additional source of origin for emboli which are carried to the pulmonary artery. Venous hyperæmia and arterial anæmia of the brain are among the consequences of uncompensated valvular lesions. The lodgment of emboli in the cerebral arteries, particularly in the middle cerebral or its branches, and the consequent softening of the anæmic portion of the brain, will be considered in Section V.

Clinical History.—Valvular lesions, so long as they involve neither obstruction nor regurgitation, give rise to no symptoms of disease, and their existence is only ascertained by means of physical signs. Lesions involving either obstruction or regurgitation, or both, as a rule do not occasion inconvenience until they have led to enlargement of the heart. Moreover, lesions

occasion suffering and are attended with danger in proportion to as the dilatation predominates over the hypertrophy.

The first symptoms proceeding from mitral obstructive or regurgitant lesions pertain to the respiratory system. Deficiency of breath on exercise is, for some time, the chief inconvenience. This progressively increases in proportion as the obstruction to the pulmonary circulation increases. The patient is at length obliged to discontinue any active muscular exertion, but may be comfortable while remaining quiet. Dyspnœa finally becomes habitual, and is more or less prominent as a symptom after dilatation of the right ventricle has taken place. A still further development of this symptom renders the patient unable to lie down, constituting, then, orthopnœa. This may be due, in a measure, to co-existing pulmonary conditions. Cough and more or less muco-serous expectoration are incidental to congestion or a low grade of inflammation of the bronchial mucous membrane. An abundant serous expectoration sometimes occurs, constituting bronchorrhœa. Hæmoptysis is not infrequent, the hemorrhage being usually small. This event generally denotes simply bronchorrhagia, but occasionally blood is extravasated into the air-cells, constituting circumscribed pulmonary apoplexy or hemorrhagic infarction. Pulmonary œdema is another intercurrent event which is liable to occur, increasing the suffering from dyspnœa. Hydrothorax is still another source of embarrassment of respiration. Pigment-induration of the lungs dependent on persistent congestion, caused by regurgitant and obstructive mitral lesions, enters into the rationale of dyspnœa in many cases.

After enlargement of the heart takes place, its action, so long as the hypertrophy predominates, is abnormally strong. This may be perceived by the hand placed over the præcordia. The patient, however, rarely complains much of palpitation, having become accustomed to the gradual increase of the power of the heart's action. The pulse is small and weak in proportion to the amount of obstruction or regurgitation, each of these immediate effects of the lesions lessening the quantity of blood propelled into the aorta and its branches by the systole of the left ventricle. The quantity of blood contained in this ventricle at the time of a systole may sometimes be so much lessened that it fails to produce a radial pulse; hence one source of intermission of the pulse; another source is an actual intermission of the ventricular systole. Inequality of the successive beats of the pulse, as regards volume and force, represents unequal supplies of blood from the left auricle to the left ventricle. Irregularity in the action of the heart is not infrequent. Intermittency of the pulse and inequality of successive beats, due to deficiency of the supply of blood to the left ventricle, are characters which denote mitral contraction rather than regurgitation.

The characters pertaining to the form of the pulse, as ascertained by the sphygmograph, in cases of mitral regurgitation, are notable variations, in the length of the line of ascent, in different pulsations, shortness of this line in a greater or less number of pulsations, its vertical direction, and marked dicrotism in the line of descent. In cases of mitral obstruction the line of ascent is longer and the variations in different pulsations are less, the direction of this line being also vertical, and the line of descent showing dicrotism. These characters denote quickness of the ventricular systole, feeble arterial tension, and want of uniformity as regards the quantity of blood sent into the aorta in different beats.

Pain is rarely a prominent symptom during the progress of mitral lesions, but uneasiness and an indefinite sense of distress, referred to the præcordia, may be complained of. Nor are there any notable symptoms referable to the nervous system. There is a marked contrast, as regards mental anxiety and

apprehension, between the cases in which the action of the heart is disturbed by lesions, and those in which the disturbance is purely functional. In the former, mental depression is proportionate to the physical suffering, and patients are apt to be apathetic with respect to danger; in the latter, the mind is depressed out of proportion to the actual ailment, and patients are harassed by imaginary fears. If dyspnœa be a prominent symptom, the loss of sleep adds to the sufferings of the patient. The sleep which is obtained is imperfect and disturbed by frightful dreams. It is not uncommon for patients to be unable to lie down for many weeks before death, short periods of sleep being obtained by inclining the body forward and resting the elbows on the knees or on some solid support.

Sooner or later, if life be not cut off by some intercurrent affection, dropsical effusion takes place into the areolar tissue and serous cavities. The lower limbs generally first become œdematous, afterward the face and body, and more or less liquid accumulates within the peritoneal and within the pleural sac. The limbs and body sometimes become greatly swollen, and the scrotum acquires an enormous size. The skin on the lower limbs, under these circumstances, may become erythematous; ulcerations or fissures are apt to occur, with abundant draining away of serum. The face is congested, and not infrequently the lips are livid. The dusky hue, due to congestion or cyanosis, combined with œdema, gives to the face an appearance which contrasts with the pallid aspect characterizing general dropsy from renal disease. General dropsy arising from mitral lesions occurs after enlargement by dilatation of the right side of the heart has taken place, and is dependent mainly on the venous obstruction which the latter condition involves. Tricuspid regurgitation, which may exist to some extent normally, is increased in this condition, and adds to the venous obstruction. This condition of the right cavities gives rise to turgescence of the cervical veins, especially when the patient is sitting or standing, and this turgescence is sometimes very great. Under these circumstances, pulsation of the superficial veins of the neck, occurring synchronously with the auricular or ventricular systole, or with both, is not uncommon. Jugular pulsation is, however, observed in some cases without venous turgescence, and when dropsy has not taken place. Other circumstances than dilatation of the right side of the heart may contribute to the occurrence of dropsy, for example, anæmia.

The organs composing the digestive system suffer from the congestion arising from dilatation of the right side of the heart. The appetite and digestion become impaired; enlargement of the liver is sometimes observed. Prior to the occurrence of dilatation, however, the appetite and digestion may be but little impaired. Nutrition may be but little affected even after the lesions have led to considerable suffering. Emaciation is not an early, nor, at any time, a marked effect of valvular lesions of the heart. The kidneys participate in the congestion, and the secretion of urine is apt to be scanty. Albumen may be present in the urine, as an effect of renal congestion, without denoting degenerative or inflammatory disease of the kidneys. Hemorrhage from the stomach or intestines is an occasional effect of the congestion of the mucous membrane in these situations. Hemorrhoids and epistaxis belong in the same category.

Aortic lesions involving obstruction or regurgitation usually give rise, as the first symptom, to inconvenience from the increased power of the heart's action, consequent upon hypertrophy of the left ventricle. The patient complains of palpitation, especially on exercise or under the influence of mental emotions. The action of the heart is felt, by the hand over the præcordia, to be inordinately strong, and the dress or portions of the body may show visible movements with each ventricular systole. Pain is more apt to be present

than in cases of mitral lesions, and, irrespective of the painful affection called *angina pectoris*, is not infrequently a prominent symptom. Cough, expectoration, dyspnœa, and hæmoptysis, dependent on pulmonary congestion, and the accidents incident thereto, occur less frequently in connection with aortic than with mitral lesions. Pulmonary congestion, dependent on dilatation of the left auricle, does not occur until the dilatation of the left ventricle becomes predominant, and the disease may end fatally without this result taking place.

If the lesions produce contraction with little or no regurgitation, the pulse is simply weakened, but not in a notable degree even when the contraction is considerable. Under these circumstances, however, the pulse is frequently weak in proportion to the power of the heart's action; the force of the stroke felt by the finger over the artery is in striking contrast to the impulse felt by the hand over the præcordia. If the lesions impair the aortic valve so as to involve considerable regurgitation, the pulse is somewhat distinctive of this fact. The artery strikes against the finger with quickness, and appears instantly to recede; the stroke is not sustained, and the pulse is said to be *jerking* or *collapsing*, giving a sensation as if a "ball of blood were shot through the artery." This is due to the fact that, directly after the ventricular systole, the aorta is emptied by the regurgitant current, and this current and the direct current come into collision when the ventricle contracts. Another symptom pertaining to the arteries, in some cases, is distinctive of free aortic regurgitation, namely, visible movements of the arterial trunks which are superficially situated, such as the carotid, temporal, subclavian, brachial, etc. The appearance caused by the movements of these vessels is sometimes very striking, and is so distinctive that aortic regurgitation is rendered highly probable by this symptom alone.

The tracings by the sphygmograph, in cases of aortic obstructive lesions, give an oblique and curved line of ascent, denoting the slowness with which the blood is driven into the aorta, and in the line of descent, dicrotism is either slight or wanting. In cases of aortic regurgitation, the line of ascent is vertical, and dicrotism in the line of descent is marked. If, as is not infrequent, senile induration of the arteries co-exist, the summit presents a plane of greater or less length; if this condition of the arteries do not exist, the upper part of the diagram representing a pulsation is pointed, and the line of ascent may be notched near its upper extremity.

General dropsy occurs in only a small proportion of cases of aortic lesions, that is, dropsy arising from the cardiac affection. This is owing to the fact that life is generally destroyed before the lesions have led to predominant dilatation of the right cavities of the heart. Hence, turgescence of the cervical veins and jugular pulsation do not belong to the clinical history of aortic lesions. This statement also holds good with respect to congestion of the abdominal viscera and the kidneys.

Aortic regurgitant lesions are apt to give rise to symptoms proceeding from a sudden increase of the accumulation of blood within the left ventricle sufficient to embarrass the action of this ventricle by distension. This ventricle becoming overloaded by the regurgitant current in addition to the direct mitral current, the ventricular walls are distended so as to weaken their power of contraction. This is a rational explanation of paroxysms of distress to which these lesions give rise. The action of the heart is irregular and spasmodic, and the patient experiences a sense of great oppression at the præcordia, with a feeling of impending death. These attacks are excited, at first, by muscular exercise or mental emotions, but, after a time, they may occur without any obvious exciting cause. They occasion great distress, and sudden death may take place in an attack of unusual violence, the left ven-

tricle being paralyzed by over-distension. They are more frequent and serious when dilatation of the left ventricle predominates over hypertrophy, yet they may be more or less frequent and violent, and may prove fatal, while hypertrophy is predominant. The occurrence of these attacks renders patients affected with aortic lesions more anxious and apprehensive than those affected with mitral lesions. As conducive to these paroxysms and the liability to sudden death, more or less importance belongs to defective circulation through the coronary arteries, which is incident to free aortic regurgitation. This defective circulation arises from the fact that the blood is forced into these arteries, not by the ventricular systole, but by the recoil of the aorta after the systole. In order that this recoil force shall affect the circulation in the coronary arteries, the aortic valves must be sufficient; if these valves be insufficient, the recoil force is expended on the aortic regurgitant current, and the heart suffers from a defective supply of blood. The weakness of the ventricles from this cause, and also from venous congestion, due to the fact that, when the heart contracts feebly, the blood within the veins of the ventricles is imperfectly expelled, conduces to paralysis, from over-distension, of the left ventricle. The danger from over-distension of the ventricle is perhaps greater without than with mitral insufficiency. The latter, as regards this danger, may be said to be compensatory.

Aortic and mitral lesions, involving either obstruction or regurgitation, or both, in each situation, are not infrequently associated in the same case. Certain of the symptomatic phenomena arising from lesions at the mitral and aortic orifice are then combined. Mitral obstruction as well as regurgitation, however, may afford some protection against the paroxysms of distress and the liability to sudden death incident to aortic regurgitation, by preventing over-distension and paralysis of the left ventricle.

Tricuspid and pulmonic lesions, as already stated are comparatively rare. In the majority of cases in which they exist, they are congenital. They are, therefore, most liable to be met with in young subjects. Tricuspid lesions, in proportion as they involve obstruction or regurgitation, lead, primarily, to dilatation of the right auricle, and thence to systemic congestion. General dropsy, under these circumstances, is likely to occur early, without having been preceded by the symptoms denoting pulmonary congestion. Turgescence of the cervical veins and venous pulsation are also early symptoms in such cases. Lesions at the pulmonic orifice, involving contraction or regurgitation, in like manner, soon lead to dilatation of the right auricle and the symptomatic phenomena dependent thereon.

Pathological Character.—The primary evils of valvular lesions are mechanical. They do harm by obstructing the direct or normal currents of blood, and by allowing abnormal or regurgitant currents to take place. They induce hypertrophy or morbid growth of the walls of the heart, by increasing the force of the heart's action, and thereby inducing hyper-nutrition. This result, it is to be borne in mind, is not an evil. The hypertrophy resulting from valvular lesions is conservative. The augmented power of action which the heart acquires with its increased muscular growth, enables it better to carry on the circulation despite the obstacles afforded by obstructive and regurgitant lesions. The hypertrophy is compensatory for the obstacles which these lesions afford. This fact has an important practical bearing on the management. Dilatation of the cavities is another result of valvular lesions. This result, when it predominates over hypertrophy, is an evil. The heart is weakened in proportion as it becomes dilated. The circulation then suffers, not only from the obstacles afforded by the valvular lesions, but from the inedequate power of the heart's action. As a rule, it is not until dilatation

predominates over the pre-existing hypertrophy, that distressing and grave symptoms of disease of the heart are developed; and the suffering and danger increase as the dilatation progresses.

It is important to bear in mind that valvular lesions do not necessarily involve existing inflammation. The atrophy and calcareous degeneration which lead to contraction of the valves, rigidity, rupture, etc., are not inflammatery processes, although they may be, and in a large proportion of cases probably are, the after-effects of inflammation.

Causation.—In the majority of cases, valvular lesions originate in an endocarditis occurring in acute articular rheumatism. The degenerative changes which follow endocarditis lead to obstruction or regurgitation after a period more or less remote. When the evils or inconvenience resulting from valvular lesions are sufficient to lead the patient to seek for medical aid, it may be found that one or more attacks of rheumatism were experienced five, ten, fifteen, or twenty years before. And when cases first come under observation, more or less enlargement of the heart has already taken place. Enlargement, indeed, has probably existed for a long time, and it may not be until the heart becomes weakened by dilatation, that the patient applies to the physician. Moreover, rupture of the valves or tendinous cords sometimes results from the violence of the heart's action, without any previous structural change. Rheumatic endocarditis affecting by preference the mitral valves. The congenital lesions generally affect the valves of the right side. On the other hand, chronic inflammation of the aorta, leading to an atheromatous condition, is apt to involve the aortic valves. These lesions are more frequent in advanced, than in early, life; whereas, the mitral lesions consequent on rheumatic endocarditis are oftener manifested in the latter period. Chronic non-rheumatic endocarditis, however, often affects both the aortic and the mitral valves, more especially the aortic segment of the latter. Valvular lesions occur not infrequently as a remote effect of syphilis.

Diagnosis.—The existence of valvular lesions can be determined with positiveness only by means of auscultatory signs. By means of signs, the existence of lesions, their situation, and their character as regards being obstructive or regurgitant, may generally be ascertained. Lesions situated at the different valves and orifices are represented by endocardial murmurs, and the presence of these is evidence of the existence and situation of the lesions. It will suffice here to enumerate the several organic murmurs produced within the heart, together with the distinctive characters of each and its significance. They are naturally arranged into mitral, aortic, tricuspid, and pulmonic murmurs.

Mitral murmurs.—A murmur heard with the first sound of the heart, *i. e.*, systolic, having its maximum of intensity at, or near, the situation of the apex-beat, or perhaps limited to that situation, represents mitral lesions. These lesions may or may not involve insufficiency of the valve and consequent regurgitation. If a regurgitant current exist, the murmur is properly called a *mitral regurgitant murmur*. But as mere roughness of the valve probably may give rise to a murmur with the characters just mentioned, without regurgitation, the name just given is not always strictly correct. A better name is *mitral systolic murmur*, with or without regurgitation. If the murmur be diffused beyond the apex, around the left lateral surface of the chest, and heard on the back near the lower angle of the scapula on the left and sometines on the right side, mitral regurgitation may be inferred. If the murmur be heard only around the apex and over the body of the heart, it does not afford proof of regurgitation; it may be a mitral systolic, non-

regurgitant, or an intra-ventricular murmur. A mitral systolic murmur, regurgitant or non-regurgitant, is not transmitted above the heart, and is not heard over the carotid arteries. This murmur may be soft (bellows-like) or rough, and sometimes it is musical.

A murmur heard after the second, and just before the first sound of the heart. *i. e.*, presystolic, continuing up to the first sound and instantly arrested when this sound occurs, also represents, generally, mitral lesions. This murmur is heard at or near the apex, and is usually confined within a circumscribed area around the apex. It is almost always rough, resembling a sound produced by throwing the lips or tongue into vibration with the expired breath. The letters, *rrrp*, whispered, the tongue vibrating with the first three letters, represent the murmur, the letter *p* representing the first sound of the heart. This murmur is produced by contraction of the mitral orifice in consequence of the union, at their sides, of the mitral curtains, forming a buttonhole-like slit. The murmur represents mitral contraction with occasional exceptions. In some cases in which free aortic regurgitation exists, the left ventricle becoming filled before the auricles contract, the mitral curtains are floated out, and the valve is closed when the mitral current takes place; under these circumstances, the murmur may be produced, although no mitral lesion exists. I have reported cases in which this murmur was marked, the autopsy showing no mitral lesions, but aortic lesions permitting free regurgitation.[1] This murmur is called the *mitral direct murmur*.

The two mitral murmurs not infrequently exist together. Either may exist without the other, the mitral regurgitant being much the more frequent.

Aortic murmurs.—A murmur with the first sound, or a systolic murmur, heard with its maximum of intensity at or above the base of the heart, and generally propagated into the carotids, is called an *aortic direct murmur*. This murmur may represent aortic lesions, and it is then called organic, or it may be due to a morbid condition of the blood, without aortic lesions, and it is then called an inorganic, an anæmic, or a hæmic murmur. The following circumstances render it probable that the murmur is inorganic or anæmic: The evident existence of anæmia; the absence of other signs of cardiac lesions; the variableness of the murmur, being sometimes present and sometimes wanting, and differing much at different times in intensity; the presence of murmur in the larger arteries, such as the carotid, subclavian, etc., and a continuous murmur in the veins of the neck commonly known as the venous hum. Attention to these points will generally suffice for determining whether an aortic direct murmur be organic or inorganic. The organic murmur denotes lesion of some kind, but not necessarily obstructive; that is, the lesion may simply render the membrane at or near the aortic orifice rough, without involving obstruction to the current. The murmur may be soft or rough, and it is sometimes musical.

An aortic murmur with the second sound of the heart, *i. e.*, diastolic, heard usually at the base, but, in most cases, having its maximum a little below the base, on or near the left margin of the sternum, is called an *aortic regurgitant murmur*. It represents insufficiency of the aortic valve and consequent regurgitation from the aorta into the left ventricle. This murmur may be more or less loud and prolonged; it is generally soft, but sometimes rough, and it may be musical. According to Dr. Balthazer Foster, if the murmur be heard at the apex of the heart, it denotes that the insufficiency is due to a lesion of the posterior segment of the aortic valve.

The aortic direct and aortic regurgitant murmur not infrequently exist in

[1] *Vide* article on cardiac murmurs, by the Author, in the American Journal of the Medical Sciences, July, 1862.

combination, but either may be present without the other. One or both of the aortic murmurs co-exist with either or both of the mitral murmurs in the cases in which mitral and aortic lesions are associated.

Tricuspid murmurs.—Tricuspid lesions are comparatively rare, and hence a murmur referable to this orifice is infrequent. A *tricuspid regurgitant murmur* occasionally exists, representing regurgitation from the right ventricle to the right auricle, with, perhaps, hypertrophy of the ventricle. It occurs with the first sound, and is to be distinguished from a *mitral regurgitant murmur* by its being either limited to, or having its maximum of intensity at, the right inferior border of the heart, namely, near the ensiform cartilage. It is apt, without care, to be confounded with a mitral regurgitant murmur. A tricuspid direct murmur is exceedingly rare owing to the fact that lesions analogous to those which give rise to a mitral direct murmur, are so infrequent at the tricuspid orifice.

Pulmonic murmurs.—A *pulmonic direct murmur* is not of very infrequent occurrence. It is with the first sound of the heart, and is heard at or above the base, over the pulmonary artery, namely, in the second intercostal space near the left margin of the sternum. It is to be distinguished from an aortic direct murmur, by its situation as just stated, coupled with its non-transmission into the carotids. It represents pulmonic lesions, when it is not inorganic or anæmic, as it not infrequently is. The circumstances which render it probable that it is inorganic are the same as when the question is as to the organic or inorganic character of an aortic direct murmur.

By means of the foregoing murmurs the diagnosis of valvular lesions is made, but it is important to bear in mind that neither the extent nor gravity of lesions is determined by the murmurs. Whether the direct murmurs are produced by lesions which involve obstruction, or not, cannot be determined by the study of the murmurs alone; and whether the regurgitant murmurs proceed from much or little regurgitation, must be ascertained by other evidence than that which the murmurs afford. The intensity of the murmurs is no proof of the gravity of the lesions; slight or innocuous lesions may give rise to loud murmurs, and grave lesions may be represented by feeble murmurs. Nor does the character of the sound as regards softness, roughness, or a musical intonation, furnish any definite information respecting the extent or gravity of the lesions. With reference to this important point of investigation, therefore, evidence is to be sought for elsewhere. Symptoms relating to the circulation, which have been considered under the head of the clinical history, shed light upon this point, but, in addition, other physical signs are to be taken into account.

A comparison of the second sound of the heart as produced, separately, at the aortic and pulmonic orifice, is one source of information. This comparison is made by listening successively to the second sound as heard in the right and in the left intercostal space near the margin of the sternum, the sound in the right side emanating from the aortic, and the sound of the left side from the pulmonic orifice. If aortic lesions be indicated by the presence of the aortic direct or regurgitant murmur, and the lesions be of such a character that the aortic valve is impaired, the second sound, as produced by this valve, will be more or less weakened, or perhaps extinguished, and the alteration is ascertained by a comparison with the pulmonic second sound. If, on the contrary, the aortic sound be unimpaired, it may be inferred that the aortic valve is intact. A comparison of the aortic and the pulmonic second sound is not less useful in the cases in which mitral lesions are shown to exist by the mitral direct or the mitral regurgitant murmur. If there be much obstruction or regurgitation, or both, at the mitral orifice, the aortic second sound will be weakened by the diminished amount of blood propelled into the aorta

with each ventricular systole; and if the mitral obstruction or regurgitation, or both, have led to hypertrophy of the right ventricle, the pulmonic second sound will be intensified by the greater force with which the blood is propelled into the pulmonary artery by the systole of the right ventricle. By means of this beautiful application of auscultation, thus, useful information is obtained respecting the extent or gravity of the lesions, the existence and situation of which are revealed by the endocardial murmurs.

Further evidence of the extent or gravity of valvular lesions relates to enlargement of the heart. Enlargement of the heart is an effect of valvular lesions, and is proportionate to the amount and duration of the obstruction and regurgitation which the valvular lesions occasion. Hence, the degree of enlargement is a criterion of the extent and gravity of the valvular lesions, and, moreover, the enlargement is a lesion of importance, as has been already seen. The question then arises, How are the existence and degree of enlargement of the heart to be ascertained? The altered situation of the apex, if not attributable to extrinsic causes, is evidence both of the existence and the degree of enlargement. The first effect of enlargement is to carry the apex to the left of its normal situation within the *linea mamallaris*. The next effect is to lower its situation to the sixth, seventh, or eighth intercostal space. In proportion as the apex is removed without the left nipple and lowered, is the amount of enlargement. The situation of the apex is to be determined by the eye or touch, or, if it can neither be seen nor felt, by finding the point where the first sound has its maximum of intensity. Other evidence of enlargement is obtained by percussion. The dulness within the area known as the superficial cardiac space, or the space in which the heart is uncovered of lung, is increased in degree and in extent, in proportion as the heart is enlarged. The left border of the heart is found by percussion to fall one, two, or three inches without the left nipple, the situation of the right border, and the base of the heart being, in most cases, but little changed.

Having determined the existence of enlargement and its extent, it remains to ascertain the kind of enlargement, that is, whether hypertrophy or dilatation predominates. The most important signs in this discrimination are furnished by palpation. If either the apex-beat, or additional impulses in the intercostal spaces above the apex, be felt by the hand to be abnormally strong, and especially if there be a heaving elevation of the præcordia with the ventricular systole, hypertrophy predominates. The apex-beat, under these circumstances, may be diffused, owing to the globular form which the heart may assume when enlarged; the augmented power of the heart's action is then to be appreciated by the impulses above the apex or by the præcordial heaving. On the other hand, if dilatation predominate, the cardiac impulses, if felt at all, are feeble. Auscultation also furnishes signs of importance in this discrimination. The first sound of the heart over the apex is loud, prolonged, and booming, in proportion as hypertrophy predominates; and, on the contrary, weak, short, and valvular if dilatation predominate. Attention to these points, in connection with the symptoms, will enable the physician to judge of the kind of enlargement to which the valvular lesions have given rise.

Prognosis.—Valvular lesions, not involving either obstruction or regurgitation, may remain for an indefinite period innocuous. The physician should be careful not to attach undue importance to the presence of one or more of the organic murmurs. These are frequently discovered in examinations of the chest when patients complain of no symptoms referable to the heart, and in persons who suppose themselves to be in perfect health. If the lesions be accompanied by enlargement of the heart, obstruction or regurgitation, or

both, may be inferred, and the lesions are not innocuous; yet, so long as the enlargement is exclusively or mainly hypertrophic, serious evils, directly attributable to the cardiac lesions, rarely occur. The patient, under these circumstances, as a rule, simply suffers more or less inconvenience. The suffering and danger, as already stated, depend chiefly on the weakness arising from predominant dilatation of one or more of the cavities of the heart. The progress of enlargement is generally slow, and it is not uncommon for patients affected with valvular lesions, together with more or less hypertrophy, to live many years, and even to old age.

The symptoms which denote danger, immediate or not remote, differ according to the seat of the valvular lesions. In connection with mitral obstructive and regurgitant lesions, habitual and considerable dyspnœa, if referable to the cardiac affection, that is, not dependent on a co-existing affection such as asthma, is evidence that the fatal termination is not very far distant. The supervention of general dropsy generally shows that the end is near at hand. Yet, sometimes, under judicious management, the dropsy diminishes or disappears, and life is prolonged for a considerable period. Death takes place suddenly in some cases in which the valvular lesions are exclusively mitral, but, as a rule, if life be not cut off by some intercurrent affection, the patient dies after a period of suffering more or less prolonged. In cases of aortic lesions involving obstruction and regurgitation, especially the latter, danger is indicated by the occurrence of paroxysms characterized by great præcordial distress, a sense of impending death, the action of the heart being irregular or tumultuous. Sudden death is liable to occur in paroxysms of this kind, the heart being paralyzed by over-distension of the left ventricle. Sudden death sometimes occurs in cases of aortic lesions when little or no habitual inconvenience from the cardiac affection had been experienced, and the existence of any affection of the heart was perhaps unknown. It is rare for lesions exclusively aortic to lead to general dropsy. The immediate or proximate danger is to be determined by the amount of obstruction or regurgitation, and more especially the latter, in connection with the degree of enlargement, and particularly enlargement by dilatation.

In cases of tricuspid and pulmonic lesions, general dropsy is an event denoting a degree of weakness of the right side of the heart from dilatation, which will be likely to lead, before long, to a fatal result.

In all cases of valvular lesions associated with much enlargement, especially if the enlargement be by dilatation, the prognosis is unfavorable; the patient will die sooner or later with the cardiac affection, if life be not destroyed by some other disease, the occurrence of a fatal result being only a question of time, and the duration varying greatly in different cases.

Death may occur in consequence of certain local affections or accidents incidental to the cardiac affection. Thus, pulmonary œdema and pneumorrhagia, incident to mitral lesions, may be the immediate cause of a fatal result. Cerebral hemorrhage may be favored by dilatation of the right side of the heart, and by hypertrophy of the left ventricle. The loss of blood by hemorrhage from mucous surfaces may, in like manner, lead to a fatal termination. The effects of emboli derived from cavities of the heart are to be included in this category.

Treatment.—The treatment, in cases of valvular lesions, has reference, *first*, to the condition of the heart as respects these lesions and co-existing enlargement; *second*, to symptoms or events incidental to the cardiac affection; and, *third*, to the general condition of the patient, the condition of the blood especially claiming attention.

Valvular lesions, so long as they are either innocuous or have not led to

enlargement of the heart, claim attention only with regard to preventing or retarding their progress. And, for this end, the strain upon the valves occasioned by the excessive action of the heart, is, as far as possible, to be avoided. Very active muscular exertions, the excitement of the circulation produced by the abuse of alcoholic stimulants and by violent mental emotions, will be likely to hasten or increase the damaging effects of the lesions. It is, however, by no means necessary to enjoin great restriction in the manner of living in these cases; it is sufficient if the habits of life be governed, in all respects, by prudence and moderation. It is not advisable, under these circumstances, for persons to consider themselves as invalids. If, as is frequently the case, the existence of the lesions be discovered accidentally, or casually, it may not be always judicious to communicate the fact to the patient. If a medical opinion be not requested, and proper hygienic management can be secured without directing the patient's attention to the heart, much needless anxiety is sometimes spared. If, however, information be desired, it should not be withheld, but explanations made which will tend to prevent an overestimate of immediate danger.

If cardiac symptoms have led the patient to apply to the physician, more or less enlargement will probably be found associated with the lesions. Let it be supposed that the enlargement which exists is mainly due to hypertrophy; it is not desirable to endeavor to diminish this hypertrophy. Inasmuch as whatever obstruction or regurgitation the lesions occasion must continue, the abnormal growth of the walls of the heart is conservative; the comfort and safety of the patient depend upon it, and measures which tend to weaken the heart will do positive harm. On the contrary, measures to maintain the muscular tone and vigor of the heart are indicated. The diet should be nutritious. The appetite and digestion, if impaired, should be improved by tonic remedies. Moderate open-air exercise is to be encouraged, very active exertions being, of course, interdicted. In short, the object is in every way to invigorate and strengthen the system.

If dilatation predominate, the measures indicated are still those which tend to give, as far as possible, tone and vigor to the heart. The labor of the circulation may be in some degree diminished by restricting the quantity of liquids ingested, redundancy of the mass of blood being in this way prevented. Especial care, however, is to be taken not to impoverish the blood. The diet is to be highly nutritious, although as dry as is compatible with comfort; tonic remedies are to be employed, and moderate exercise out of doors is still advisable. In proportion as the powers of the system are lowered, the heart is weakened, and dilatation favored. The object of management is, by strengthening and invigorating the system, to retard the progress of dilatation.

Thus far the treatment has reference to the condition of the heart. Of the symptoms incidental to the cardiac affection, irregularity, undue frequency, and feebleness of the heart's action call for treatment. The appropriate remedies are those which diminish the frequency, restore the rhythm, and strengthen the action of the heart. Digitalis is an invaluable remedy, regulating the heart's action without diminishing, but, on the contrary, increasing the power of the ventricular contractions. The conclusion from my own experience accords with that of many observers of late years with respect to this remedy, namely, that, as regards its effect upon the heart, it may properly be called a cardiac tonic. The remedy is, therefore, particularly suited to cases in which the action of the heart is rendered irregular and feeble by dilatation, and it is not suited to cases in which the symptoms and signs denote hypertrophy.

Fothergill, who has studied the effects of this remedy clinically and by

experimentation on lower animals, gives the following as the rationale of its salutary operation: "Digitalis excites more perfect ventricular contraction, the arteries are better filled with blood, and consequently the heart itself is better nourished, while the brief diastolic sleep is lengthened. Betwixt the longer rest and the improved nutrition, the heart is enabled to grow and to increase in power."[1]

The fact that the diminished frequency of the heart's action is due to lengthening of the diastole renders important a cautious use of the remedy in cases of free aortic regurgitation; yet, a considerable increase of the power of the ventricular contraction may be a gain overbalancing any risk of overfilling of the ventricular cavity from an increased diastolic rest. The pulse, the apex beat, and the intensity of the first sound of the heart, together with the subjective symptoms, enable the physician to judge of the safety and utility of the remedy in these cases. There is little ground for the traditional notion that digitalis is peculiarly a cumulative remedy, the patient being liable to a sudden manifestation of its toxic effects. This remedy is especially useful in cases of enlargement dependent on mitral regurgitant lesions.

Digitalis in moderate doses (a grain or two of the leaves, two or three drachms of the infusion, from ten to fifteen minims of the tincture, or one-sixtieth of a grain of digitalin twice or thrice daily) is often well tolerated, and may be continued with advantage for a long period. Not infrequently, however, after a time it causes gastric disturbance which is sometimes avoided by changing the form of the remedy or by the addition of a carminative. Generally it is advisable to discontinue it when its good effects have been obtained, resuming it according to circumstances.

Aconite is a useful remedy when the action of the heart is rapid, and may be substituted for digitalis if the latter be not tolerated. It is not, however, a substitute for digitalis in respect of a tonic effect on the heart. It is especially applicable to cases in which disturbance of the heart's action is due to functional disorder superadded to lesions, and when the action is not notably weakened by dilatation.

It has been claimed for belladonna that it is a heart tonic. This is problematical; but, as a neurotic sedative, it is sometimes of service, in this respect belonging in the category of other sedatives—hyoscyamus, hydrocyanic acid, gelsemium, etc. A belladonna plaster over the præcordia has a good effect. I have known it to dilate the pupil. Nauseant sedatives of the veratrum viride are not appropriate. The latter lessens the frequency, but also the strength of the heart's action. Nux vomica or strychnia appears, either directly or indirectly, to have a tonic influence upon the heart. Cafeine, or an infusion of coffee, as a transient cardiac stimulant, has some value. For the symptoms incident to aortic regurgitation, Sibson recommends, as a palliative remedy, the infusion of senega in doses of from half an ounce to an ounce, combined with an equal quantity of the aromatic spirits of ammonia or five grains of the carbonate of ammonia.

For the relief of the dyspnœa which accompanies excessive dilatation associated with mitral lesions, ammonia, the ethers, and dry cups applied to the chest afford relief. Notable relief is obtained often by a brisk hydragogue purgative from time to time. So far from inducing weakness of the heart's action or general prostration, the effects of this measure are in these cases the reverse. Bronchorrhœa is not to be checked by opium, but small doses, administered hypodermically or otherwise, not infrequently afford relief, and are not hurtful if the patient do not suffer from the after-effects of this drug.

[1] The Heart and its Diseases, 1879.

Dyspnœa and other pulmonary symptoms are sources of suffering in certain cases. So far as they are dependent on the cardiac affection, all that is to be expected from treatment is palliation. The ethers and mild revulsive applications to the chest or dry cupping may mitigate the dyspnœa. Opiates to check expectoration will be likely to increase the distress instead of affording relief.

General dropsy is an event requiring treatment. Diuretic remedies should be first tried, and, if these prove inoperative, hydragogue cathartics are to be resorted to. Of these, elaterium is the most efficient. Given in small doses, this remedy may often be continued for a long period without producing depression. The bitartrate of potassa with jalap, and podophyllin are valuable hydragogues. The Epsom salts answer exceedingly well in many cases; they are reliable, in general well tolerated, and the amount of hydragogue effect is easily regulated. If only a mild hydragogue effect be desired, the bitter waters—Pulna, Friedrichshall, and Hunyadi Janos—may suffice. In the majority of cases only partial and temporary relief of the dropsy is procured, but in some cases it is completely removed, and it may not return for a considerable period. Diuretic remedies sometimes act very efficiently. They are more likely to effect the absorption of the effused liquid in cases of dropsy dependent on diseases of the heart than in cases of renal dropsy; in the latter cases, the kidneys, being diseased, rarely respond to diuretics. I have known the infusion of parsley-root to act with wonderful power as a diuretic remedy. If the anasarca be so extreme that the limbs become enormously distended, numerous punctures may be made with the point of a pin, not very sharp, the punctures being so slight as not to draw blood, and through them a large amount of liquid will sometimes escape, affording, for a time, marked relief. Vesications or cracks in the integument of the lower limbs, in some cases, occur as a consequence of the distension, giving exit to an abundant flow of serum, with relief. Incisions or deep punctures are attended with a risk of gangrene. In the treatment of the dropsy, restriction of the amount of ingested liquid, as far as is compatible with comfort, is important.

A highly important part of the treatment relates to the general condition of the patient, and especially to co-existing anæmia. Anæmia is not infrequently associated with the lesions under consideration, and, as a consequence, functional disorder of the heart is superadded to the disturbance caused by the lesions. Irregular action of the heart, or excessive action, dyspnœa, and even dropsy, may be due to the superadded functional disorder. The error is not infrequently committed of attributing the symptoms in such cases exclusively to the lesions, and forming a prognosis more unfavorable than the latter actually warrant. By removing the anæmia the symptoms are relieved, and the patient may even seem to recover completely from the cardiac affection. Anæmia existing in connection with valvular lesions claims appropriate treatment, namely, removal of the cause if it be apparent, for example, lactation, the employment of chalybeate tonics, with nutritious diet and other hygienic measures. Such cases call for a certain amount of reserve in referring the symptomatic phenomena to the lesions. Exclusive of anæmia, the general condition of the patient should be improved and maintained at the highest possible point of strength and vigor. As a rule, in proportion as alimentation, digestion, assimilation, and nutrition are approximatively normal, the grave effects of heart-lesions are less likely to occur; in other words, the lesions are best tolerated. The importance of a nutritious diet, remedies to promote digestion if it be defective, and hygienic agencies conducive to the welfare of the body, cannot be too strongly enforced as promoting tolerance and prolonging life.

CHAPTER IV.

HYPERTROPHY AND DILATATION OF THE HEART. ATROPHY, OBESITY, FATTY DEGENERATION. PARENCHYMATOUS DEGENERATION, AND THROMBOSIS OF THE HEART. EMBOLISM OF THE PULMONARY ARTERY.

Hypertrophy and Dilatation of the Heart.

THESE conditions will be considered together, inasmuch as they are usually combined with each other. They may affect the whole heart or certain sections of it, and are, therefore, classified as total and partial hypertrophies and dilatations. The most important classification, however, is that based on the capacity of the heart cavities. In *simple hypertrophy* the cavity is of normal size, in *eccentric hypertrophy* it is dilated. In *simple dilatation* the muscular wall is of normal thickness, in *hypertrophic dilatation* the wall is hypertrophied, in *atrophic dilatation* it is thinned. Hypertrophic dilatation is often employed in the same sense as eccentric hypertrophy. Rokitansky, however, proposed to apply the term eccentric hypertrophy to enlarged hearts in which the hypertrophy predominates over the dilatation, and hypertrophic dilatation or, as he called it, active dilatation, to cases in which the dilatation is decidedly in excess of the hypertrophy. Of the different varieties, eccentric hypertrophy is by far the most frequently observed. Some writers have assumed the existence of a concentric hypertrophy, a condition in which the muscular wall is thickened and the cavity diminished in size. Great caution, however, is required in estimating the capacity of the ventricles after death. If the heart be found firmly contracted, its cavities seem smaller and its walls thicker than normal. It is probable that cases of supposed concentric hypertrophy are only those of firmly contracted normal or hypertrophic hearts. It is also necessary not to mistake a relaxed and flabby heart, such as is often found after death from acute infectious diseases, for a heart affected with dilatation. In so-called simple dilatation the heart is evidently hypertrophied, as the normal thickness of the muscular walls could not otherwise be preserved. In fact, hearts affected with dilatation and thinning of the walls, that is, with so-called atrophic dilatation, usually weigh more than normal, and are therefore hypertrophied. Simple hypertrophy is infrequent. It may be found in connection with certain forms of chronic Bright's disease.

In a given case, it is important to determine the degree of dilatation in proportion to the hypertrophy, for, while hypertrophy strengthens the muscular power of the heart, dilatation enfeebles it; the latter is, therefore, much the graver of the two conditions, giving rise to nearly all the symptoms.

If the enlargement be confined to the right side of the heart, the organ is increased chiefly in breadth and has a more rounded, less conical shape than normal. The rounded apex is formed by the right ventricle. When the left ventricle is hypertrophied, the heart is elongated, the apex being lower down and further to the left than normal, and, if hypertrophy be combined with dilatation, the septum ventriculorum is pushed over to the right side, encroaching upon the cavity of the right ventricle. If the whole heart be enlarged, its shape is triangular with rounded angles. The name *cor bovinum* has, from ancient times, been applied to a heart enormously enlarged. The degree

of hypertrophy varies much in different cases. The weight in the majority of hypertrophied hearts falls between twelve and twenty ounces. Hope mentions one weighing forty-four ounces, and Stokes one which yielded the enormous weight of four pounds two ounces, avoirdupois. In determining a small amount of hypertrophy, it is necessary to take into consideration the variations in weight within physiological limits; also the age and general physique of the individual.

Hypertrophic heart-muscle is brownish-red in color and firm, almost board-like, in consistence. The wall of an hypertrophied right ventricle has a peculiarly tough, leathery consistence. After incision the walls remain open and rigid. Both color and consistence will be modified if the hypertrophic muscle have undergone fatty degeneration, which is not infrequent.

There has been much discussion as to whether, in hypertrophy of the heart, new muscle-fibres are produced, or the preëxisting muscle-fibres simply increased in volume. The formation of new muscular fibres and the proliferation of the muscular nuclei seem to be established. It is probable that enlargement of the muscular fibres also occurs, as was accepted by the older writers.

Hypertrophy and dilatation of the heart are secondary affections, and consecutive in the majority of cases to some mechanical obstacle to the circulation. The obstacle may be seated in the heart itself, or in the pulmonic, or the systemic, circulation.

The causes, seated in the heart, of hypertrophy and dilatation are—

1. Stenosis and insufficiency of the valves in front.
2. Insufficiency of the valves behind.
3. Chronic pericarditis and pericardial adhesions.
4. Myocarditis with or without partial cardiac aneurism.
5. New growths in the heart.

Weakening of the cardiac muscle from parenchymatous and from fatty degeneration, leads to dilatation of its cavities.

The obstruction may be in the pulmonic circulation, in which case only the right side of the heart enlarges. The most important of these causes are—

1. Pulmonary emphysema.
2. Long-continued and large pleuritic effusions.
3. Stenosis of the pulmonary artery, either as a primary change in the artery itself, or by pressure from without as by aneurisms of the aorta, tumors, etc.
4. Curvatures of the spine, causing compression of the lungs.

Obstructions in the aortic system, causing hypertrophy and dilatation, are—

1. Atheroma of the aorta and larger arteries. Many cases of senile hypertrophy are referable to this cause.
2. Narrowing of the calibre of the aorta, either as a congenital condition, or by pressure from without as by tumors, etc.

It is important to notice that, contrary to former belief, aneurism of the aorta does not lead to hypertrophy of the left ventricle. This has been demonstrated by the investigations of Axel Key.[1] Aneurism of the aorta alone does not tend to increase the tension in the left ventricle. Very often, however, an atheromatous condition of the aortic valves is associated with aneurism, and the former may be the cause of ventricular hypertrophy.

A well-recognized form of cardiac hypertrophy is that which is secondary to certain forms of chronic Bright's disease, particularly to the small, granular kidneys. The explanation of this is not thoroughly understood, and will be referred to under the head of Bright's disease. Suffice it to say here, that it is probably due to some resistance to the blood current through the small

[1] Key, Nordiskt med. Arkiv, Bd. I., 1870.

vessels. This form may be simple hypertrophy, but it is usually eccentric. All of the other forms of cardiac hypertrophy are eccentric. An index to the degree of distension to which the ventricular cavity is subjected, is afforded by the condition of the papillary muscles. Thus, in aortic insufficiency, which is attended with great increase of pressure in the left ventricle, the papillary muscles of this ventricle are found elongated, flattened, and in part fibrous, especially at the origin of the chordæ tendineæ; in the simple hypertrophy of Bright's disease, on the other hand, the papillary muscles are enlarged and rounded.

The name primary hypertrophy of the heart has been given to cases in which the disease has been attributed to habitual over-exertion of the muscular system, and to repeated nervous excitation of the heart. Peacock, Seitz, Da Costa, and others have called especial attention, of late years, to cardiac hypertrophy and dilatation referable to over-exertion, especially in the case of soldiers who have done heavy marching in a campaign. Their observations have rendered it probable that long-continued, severe muscular strain is an important element in the production of hypertrophy and dilatation of the heart, but the infrequency with which these affections occur, under the conditions named, leads to the inference that an additional factor, not yet understood, enters into their causation.

The hypertrophy, without valvular lesion, which has been sometimes observed in cases of Graves' or Basedow's disease (exophthalmic goitre) may perhaps be referred to excitation of the nervous apparatus of the heart.

Hypertrophy and dilatation of the heart are sometimes found as apparently idiopathic conditions, when they cannot be referred to any cause.

The symptoms of hypertrophy are referable to the increased power of the heart's action. Hypertrophic enlargement of the left ventricle leads to an abnormal force of the current in the systemic arteries; the pulse is strong and full, the face flushed, active cerebral congestion is favored, and certain symptoms, such as pain, vertigo, *tinnitus aurium*, are attributable to the latter. The patient feels the powerful action of the heart, but he becomes accustomed to it, and it may occasion but little annoyance.

If the hypertrophy have been induced by an impediment to the circulation, it is conservative, as when it proceeds from valvular lesions, and is not, therefore, to be regarded as an evil. It may, however, lead or contribute to serious accidents. It is intelligible that hypertrophy of the left ventricle, without valvular lesions (these being, in a measure, protective), may favor cerebral hemorrhage in cases in which the arteries of the brain have become weakened from degenerative changes. In like manner, it is not improbable that hypertrophy of the right ventricle may sometimes contribute to pulmonary hemorrhage.

The diagnosis of hypertrophy must rest on physical signs which are the same as when the hypertrophy is associated with valvular lesions. The fact of enlargement and its degree are determined by the altered situation of the apex-beat, together with the enlarged area of the superficial and the deep cardiac space. That the enlargement is due, either exclusively or mainly, to hypertrophy, is determined by the abnormal force of the impulses of the heart, and by the prolongation, intensity, and booming character of the first sound.[1] The absence of endocardial murmurs is the basis of the conclusion that the enlargement is not connected with valvular lesions.

Hypertrophy, when conservative or compensatory, of course does not claim treatment. If it be congenital, or there be sufficient grounds for considering

[1] *Vide* preceding chapter.

it otherwise than conservative, measures to prevent further growth and to obviate accidents are called for. Bloodletting and other measures which impoverish the blood are not indicated. Anæmia, by rendering the heart unduly excitable, involves additional inconvenience and danger. Excessive action of the heart may be moderated by tranquillizing remedies, such as aconite, hydrocyanic acid, and belladonna. In the cases of hypertrophy disconnected from valvular lesions observed by Da Costa among soldiers, marked benefit was obtained by the use of aconite, one or two drops of the tincture being given twice or thrice daily, and continued, without any increase of the dose, for months. The diet should be sufficiently nutritious, but unstimulating. Alcoholics are to be interdicted. Liquids should be taken sparingly. Active muscular exercise and emotional excitement are to be avoided.

Dilatation of the cavities of the heart may accompany hypertrophy without, as well as with, valvular lesions. If there be causes giving rise to hypertrophy, which continue after the morbid growth has reached its limit, dilatation of necessity follows, and, in time, will become predominant. But, in most cases, excessive dilatation proceeds from weakness of the muscular walls, arising from fatty degeneration and other causes. The muscular walls may yield to distension, and dilatation take place when there is no abnormal impediment to the circulation; and dilatation, however induced, tends progressively to increase.

The symptoms of predominant dilatation are referable to weakness of the heart's action. This weakness is shown by feebleness of the pulse, coolness and cyanosis of the surface; and, if the right cavities become considerably dilated, general dropsy ensues. Fatal syncope may occur from an over-accumulation of blood in the cavities in cases in which the organ is greatly enfeebled by dilatation. The physical signs show enlargement of the heart; and that the enlargement is due to predominant dilatation is shown by the feebleness of the cardiac impulses, and by the weakness, shortness, and valvular quality of the first sound as heard over the apex. The absence of valvular lesions is inferred from the absence of endocardial murmur.

Of the two lesions, hypertrophy and dilatation, the latter is by far the more serious. The indications for treatment are the same as when the dilatation is in association with valvular lesions, the object in general terms, being to endeavor to improve the tone and vigor of the muscular walls.

Atrophy of the Heart.

Simple wasting or atrophy of the heart is found in emaciated persons as part of the general marasmus. Diseases attended with prolonged cachexia, notably carcinoma and chronic pulmonary tuberculosis, are apt to lead to atrophy of the heart. An abnormally small size of the heart has been observed as a congenital condition in connection with imperfect development of the whole circulatory system, frequently combined with arrested sexual development. Senile marasmus may be accompanied with cardiac atrophy, but not infrequently it is associated with hypertrophy in consequence of atheroma of the large arteries. Pressure upon the heart from without, as by tumors, pericardial and pleuritic effusions, has also been adduced as a cause of atrophy. It has been referred to atheroma of the coronary arteries. Atrophy of the left ventricle results from uncomplicated stenosis of the mitral orifice as has been already stated. The heart may be reduced to four ounces in weight. In a case under my observation the weight was four and a half ounces. The coronary vessels, taking no part in the atrophy, appear tortuous and prominent upon its surface. Atrophied hearts are sometimes covered with a considerable amount of adipose tissue which may obscure the actual reduction in size of the myocardium.

Atrophy of the heart usually presents itself in the form of so-called brown atrophy. The wasted muscle has a brownish color, and under the microscope the muscular fibres are found to contain little granules of yellowish-brown pigment, accumulated especially about the nuclei. A similar pigmentation, but in less degree, is not uncommon in normal hearts.

In a clinical point of view this lesion is unimportant. It occurs under circumstances which divest it of evil consequences, if, indeed, it be not a conservative process.

Fatty Degeneration. Obesity of the Heart.

By obesity of the heart (called also fatty infiltration, deposition or growth) is understood the accumulation of adipose tissue upon the surface of the organ and between the muscular fibres. This condition is met with in corpulent subjects, and sometimes without general obesity, especially in the bodies of old people and drunkards. The fat accumulates first in the sulci in the course of the coronary vessels, and it may eventually cover the whole right and most of the left ventricle. A moderate accumulation of fat upon the outside of the heart cannot be considered of any importance; but when the fat is excessive in amount, and especially when it penetrates deeply into the myocardium, the muscular fibres become atrophied from compression, and the heart is enfeebled. It will be observed that in obesity of the heart the muscular fibres suffer only in so far as they are compressed.

In fatty degeneration, the muscular substance is metamorphosed into fat which appears in a granular form in the muscular fibres. By fatty heart or Quain's fatty degeneration is understood this form. Fatty degeneration may attack a heart previously diseased, or the organ may have been previously healthy. In the former case the degeneration may be localized in the affected portion of the heart; in the latter instance the whole heart becomes fatty, but not of necessity in an equal degree in all parts. The fatty heart is of a pale yellowish color and soft in consistence. The yellowish color is usually more marked in certain parts than in others. It is usually most noticeable in the inner layers of the myocardium, which are particularly prone to fatty degeneration. These layers, as seen through the endocardium, especially in the papillary muscles of the left ventricle, present a peculiar mottled appearance which is quite characteristic. The fatty degeneration may be confined to the inner part of the myocardium.

Examined under the microscope, the muscular fibres are found clouded by the presence of large numbers of granules and small globules of fat frequently arranged in longitudinal rows inside of the muscular substance. The transverse striation is obscured or entirely obliterated. Some fibres are more affected than others. A small number of fatty granules is not uncommon in the cardiac muscle; when of clinical importance the degeneration is in such amount that it can usually be recognized with the naked eye. The fatty material is undoubtedly a product of the metamorphosis of the albuminous substance of the muscle.

The parenchymatous or granular degeneration to be presently described, which accompanies many acute infectious diseases, such as typhoid, remittent, and puerperal fevers, acute yellow atrophy of the liver, etc., may be followed by a more or less extensive fatty degeneration.

The symptoms which make up the clinical history of fatty degeneration of the heart, are due to its inability to carry on effectively the circulation. Degeneration of the left ventricle occasions feebleness of the pulse. The pulse is apt to be irregular and intermittent. It has been observed to be

notably infrequent, the number of beats sometimes falling as low as twenty per minute. It is probable that, in some instances, the infrequency of the pulse was owing to many of the ventricular systoles being too feeble to propel the blood with sufficient momentum to be felt at the radial artery. Dyspnœa, especially on exercise, is more or less prominent as a symptom, according to the feebleness with which the circulation through the pulmonary circuit takes place; this symptom is more marked when the right ventricle is affected. Paroxysms of syncope are liable to occur, accompanied by a sense of præcordial oppression and distress. These denote distension of the cavities from an accumulation of blood. Accompanying these, paroxysms of pain referred to the præcordia, and sometimes extending to one or both upper extremities, more especially on the left side (*vide* Angina pectoris), are not uncommon. The remarkable rhythmical irregularity of breathing known as the "Cheyne-Stokes respiration," is sometimes observed, but it is by no means diagnostic of this lesion.[1] It occurs in uræmia, in certain cerebral affections, and in connection with other cardiac lesions. Seizures resembling apoplexy, characterized by temporary loss of consciousness, without paralysis, the surface being pallid and cool and the circulation extremely feeble, have been observed in persons who have subsequently died of this affection. These pseudo-apoplectic seizures, in some cases, have been of frequent recurrence.

Feebleness of the circulation, however, in an equal degree, may proceed from dilatation either with, or without, valvular lesions. The existence of fatty degeneration, therefore, cannot be ascertained positively by means of the symptoms alone. Other circumstances and the physical signs are to be taken into account in order to arrive at a diagnosis. The signs which accompany this lesion are, feebleness or absence of cardiac impulse, weakness of the heart-sounds, more especially the first sound, this sound sometimes suppressed over the apex, and, if heard, short and valvular like the second sound. These signs are equally present when the heart is considerably or greatly dilated, and they denote fatty degeneration only when the organ is found not to be sufficiently enlarged to refer them to dilatation. Sex is of some weight in the diagnosis, men being the subjects much oftener than women. The age of the patient is to be considered. Fatty degeneration very rarely occurs in the male under fifty, and in the female under forty years of age. Of 88 cases collected by Hayden, the larger number were in persons between sixty and seventy years, the remainder being between forty and fifty. The evident tendency to deposits of fat elsewhere has not great weight in the diagnosis, inasmuch as fatty degeneration of the heart occurs in lean subjects as well as in those prone to corpulency. The presence of the *arcus senilis* possesses some diagnostic importance, although clinical observation has abundantly shown that this fatty change in the cornea occurs without degeneration of the heart, and *vice versâ*. The habits of the patient are to be considered with reference to diagnosis. This lesion occurs in persons of sedentary or indolent habits as regards muscular exertion, and who are addicted to the pleasures of the table. The habitual use of alcoholic liquors favors its occurrence. Giving due attention to the foregoing points, the existence of fatty degeneration may often be determined with much positiveness. If valvular lesions and dilatation be present, its existence is ascertained with less positiveness. Under these circumstances, it is to be suspected when, in addition to the diagnostic points

[1] This phenomenon is described by Stokes "as a form of respiratory distress, consisting of a period of apparently perfect apnœa (*i. e.* absence of breathing), succeeded by feeble and short inspirations, which gradually increase in strength and depth until the respiratory act is carried to the highest pitch of which it seems capable, when the respirations pursuing a descending scale, regularly diminish until the commencement of another apnœal period."

just named, the valvular lesions and enlargement appear to be inadequate to account for the feebleness of the heart's action.

To give rise to symptoms which point to the heart as the seat of disease, the amount of fatty degeneration must be considerable. A small or moderate amount may not occasion sufficient weakness to give rise to any notable symptoms. More or less degenerative change is not infrequently found after death in cases in which it had not been suspected during life. Existing in a small or moderate amount, however, it may constitute an important element in various diseases, rendering the system less able to resist them, and also less able to bear bloodletting and other therapeutical measures which tend to enfeeble the circulation. Existing in a considerable or great amount, it is a grave lesion. In such cases it involves a liability to sudden death. Death may take place from rupture of the ventricular walls. This occurs oftenest in the left ventricle near the apex. In the great majority of the cases of this accident, it arises from softening incident to fatty degeneration. The occurrence of sudden death, when rupture does not take place, is accounted for by over-accumulation of blood within the cavities, and consequent paralysis of the muscular walls from distension.

With reference to treatment, causal indications are often not determinable with precision in individual cases. The connection with habits of indolence, over-feeding, and the use of alcoholics, has been already stated. These causes relate only to a certain proportion of cases, and in these they have, perhaps, only an accessory influence. Clinical observation, indeed, appears to show that defective nutrition is oftener concerned in the causation. The lesion is found in those who are under, as well as those who are over, fed. General anæmia, especially pernicious anæmia, is causative. The lesion is not of frequent occurrence in connection with simple or benign anæmia. Defective nutrition of the heart from local causes, in not a small proportion of cases, is, intelligibly, an etiological condition. Thus it is incident to obstruction of the coronary arteries by calcification or embolism, and to defective circulation as a consequence of impaired recoil of the aorta from atheroma or aortic insufficiency. It is sometimes a sequel of pericarditis and myocarditis. It participates in the acute degeneration of other organs in poisoning by phosphorus, and, it is said, also by mineral acids. Local and general causative conditions may be associated; but there are instances in which it cannot be distinctly traced to any appreciable causes. The pathological character of this lesion has been considered in Part I. (*Vide* page 55.)

The objects of treatment are to prevent the further progress of the lesion, and to develop the muscular vigor of the heart to the extent of its capability for improvement in this respect. The diet should be nutritious, consisting of animal food in as large proportion as is compatible with the appetite and digestion. Fatty food is to be interdicted. Farinaceous and saccharine articles should form a moderate proportion of the diet. Liquids should be restricted as much as possible. Alcoholic stimulants should be taken in moderation, if at all. Moderate exercise out of doors is highly important; it should not be carried, of course, to the extent of overtasking the heart, but taken within the limits of comfort, that is, so as not to occasion hurried circulation, præcordial oppression, or dyspnœa. On the other hand, considering the liability to rupture and to sudden death from paralysis of the heart due to an over-accumulation of blood within the cavities, an important part of the management is to enjoin avoidance of violent muscular exertions and mental excitement. The patient should be cautioned against running, lifting, straining at stool, etc. Exposure to cold may involve danger. The surface of the body should be well protected against changes of temperature.

The hygienic is far more important than the medicinal treatment. Yet

remedies may be highly useful. Tonic remedies are generally indicated. The appetite and digestion, if impaired, are to be improved as much as possible. If the patient be anæmic, this condition claims appropriate treatment. Coexisting disorders of any kind are to be relieved. The symptomatic effects of weakness of the heart will claim palliative measures. Attacks of syncope and pseudo-apoplexy require ethereal and alcoholic stimulants. Irregular action of the heart may be relieved by hydrocyanic acid and digitalis. Dyspnœa, general dropsy, and other effects call for the same palliative measures as when they proceed from dilatation of the heart.

By judicious management, life and comfortable health may be maintained for a long period, notwithstanding the existence of this lesion in a considerable amount.

Parenchymatous Degeneration.

In parenchymatous, as in fatty, degeneration, the muscular substance is clouded, and the striæ more or less obscured by the presence of a granular material, but in the former the granules are albuminous, in the latter fatty. Granular degeneration, albuminous degeneration, and cloudy swelling are synonymous terms for this affection. The name parenchymatous inflammation is sometimes used improperly in the same sense. Many of the cases formerly described as simple softening of the heart belong in this category. The degeneration affects the whole muscular substance of the heart. The heart is paler and of softer consistence than normal. The granules of parenchymatous degeneration are paler, less glistening, and usually smaller than those of fatty degeneration, from which they can be distinguished by their solubility in acetic acid and insolubility in ether. The granules consist in some modification of the pre-existing albuminous substance, but it is not known in what this modification consists.

Parenchymatous degeneration is found chiefly after death from acute infectious diseases, such as typhus and typhoid fevers, puerperal fever, the exanthematous fevers, erysipelas, cerebro-spinal meningitis, pyæmia, and septicæmia, also in consequence of extensive burns and of poisoning by phosphorus, arsenic, etc. It can be produced artificially in animals by exposure to high temperatures, but the influence of this cause in man has been exaggerated. Severe blood-poisoning is the most efficient cause. The degeneration may be developed with great rapidity. Proof of this is afforded by a case observed by Wagner,[1] who found this change in the heart and kidneys of a previously healthy girl who died six hours after extensive burns. Fatty degeneration is a frequent accompaniment and sequence of parenchymatous degeneration, but there is no necessary connection between the two processes. Without doubt parenchymatous degeneration occurs in the course of many diseases which end in recovery (Part First, page 54).

This lesion explains the weakness of the circulation out of proportion to the adynamia or general debility in certain diseases. The symptoms and signs are those which represent notable feebleness of the heart's action. As regards the signs, diminished intensity of both sounds, but more especially of the first sound, characterizes the feebleness from this as well as from other lesions. These signs contra-indicate depletory or debilitating measures of treatment, and, on the contrary, furnish a reason for supporting treatment, in addition to the indications derived from the general condition of the system.

[1] Wagner, Handbuch des allgem. Pathol. p. 413, Leipzig, 1876.

New Growths and Parasites in the Heart.

These have no distinctive clinical history, and, therefore, will receive only the briefest mention here. The most common new formations in the heart are tubercles and gummata. Miliary tubercles are frequently found in the heart in cases of acute general tuberculosis. They should be sought for especially in the endocardium of the conus arteriosus of the right ventricle. Tubercles in the myocardium may give rise to myocarditis (tuberculous myocarditis). Further than this it is not known that they give rise to any symptoms. Cardiac gummata and syphilitic myocarditis have already been referred to under the head of myocarditis. Carcinoma, sarcoma, lipoma, fibroma, myoma strio-cellulare, have been observed in the heart. Echinococcus cysts, and more rarely cysticercus cellulosæ, have been found in the heart.

The interesting subject of congenital malformations and diseases of the heart does not come within the scope of this work. The reader is, therefore, referred to works on pathological anatomy, and to special treatises on the subject, including those devoted to diseases of infants, for information concerning the morbus ceruleus or blue disease, non-closure of the foramen ovale, of the ductus Botalli, of the septum ventriculorum, stenosis of the pulmonary orifice and artery, etc.

Rupture of the Heart.

As already stated (*vide* page 356), this accident is generally incident to fatty degeneration, and it is most apt to occur when the degeneration is circumscribed. It occurs, however, as an effect of cardiac aneurism, myocardiac abscess, and extravasation of blood from rupture of a branch of the coronary artery. It very rarely happens in persons under sixty years of age. Usually it causes instant or speedy death; but, if the perforation be small, it may be temporarily plugged by a clot, and life continue for hours and even days. I have known death to be delayed for six hours after the symptoms denoted the occurrence of the rupture. The symptoms are those which sudden compression of the heart by the accumulation of blood in the pericardium would be expected to produce, together with the loss of blood. In most cases, however, there is no time, before death, for the observation of symptoms. Rupture has been repeatedly observed to occur in connection with a paroxysm of præcordial pain resembling angina pectoris.[1] In a case which came under my observation, the patient, a middle-aged man, had had repeated attacks of severe angina, and the heart gave no evidence by physical signs of disease. Death occurred suddenly, and a rupture was found of the left ventricle. The rupture took place within a circumscribed space in which there was advanced necrosis, the muscular wall being much softened. A branch of the left coronary artery leading to the necrosed space was completely occluded by a thrombus, and there was partial atheromatous occlusion of both coronary arteries. Except at the necrosed space, the heart had not undergone fatty degeneration.

Thrombosis of the Heart. Embolism of the Pulmonary Artery.

If is important to distinguish ante-mortem thrombi from the coagula formed after death. At autopsies the right ventricle and auricle are usually found to

[1] For an analysis of 24 cases of spontaneous rupture of the heart, by Barth, *vide* Archives Générale de Médecine, Paris, 1871. For an analysis of over 100 cases, by Quain, *vide* London Lancet, 1870.

contain coagulated blood. These coagula are often in great part devoid of blood-coloring matter, and constitute the so-called decolorized post-mortem clots. The blood in these cases coagulates so slowly after death that the red blood-corpuscles have time to sink, hence the upper layers of the clot consist mostly of fibrin and white blood-corpuscles, the latter being of lighter specific gravity than the red corpuscles. These post-mortem clots are yellowish-white, succulent, loosely attached to the heart-walls, and send offshoots into the pulmonary artery and its branches. They receive the imprint of the valves and other irregularities with which they lie in contact. They have no clinical significance.

Fibrinous deposits may form in the heart during life. The usual causes of their formation are the same as those of the production of thrombi in general, namely, slowing of the circulation and roughening of the inner layer of the vessel. The presence of fibrinous deposits on the roughened endocardium, especially of the valves, in acute and in chronic endocarditis, has already been mentioned (p. 324). Cardiac thrombi are liable to form in consequence of the slow circulation attending excessive dilatation of the heart and fatty heart. These are called marantic thrombi. They form especially in the recesses of the heart, where there is a natural obstacle to the propulsion of the blood. They are to be sought, therefore, particularly in the appendices auricularum, and between the columnæ carneæ, especially on the right side of the heart. They also form in cardiac aneurisms. When these thrombi attain to a considerable size and project into the heart cavities, they are often called cardiac polypi. These ante-mortem thrombi are of a whitish, yellowish, or reddish-gray color, dull in appearance, adherent to the heart-wall, often friable in consistence, laminated in structure and with the free surface usually rounded (végétations globuleuses of Laënnec). The central portion of the older thrombi is often broken down into a creamy mass which was formerly mistaken for pus, and such thrombi were called puriform. This creamy mass consists chiefly of granular material. The thrombus itself is composed mostly of fibrin and white blood-corpuscles, and belongs to the so-called white thrombi, described accurately by Zahn (page 29).[1] Cardiac thrombi are usually small in size, but they may take up the greater part of one of the heart cavities, and may even extend from one cavity into another.

The formation of thrombi, within the right ventricle, of considerable size (heart-clot) has been referred to especially in connection with acute lobar pneumonia or pneumonic fever, and also as an accident, occurring in connection with other diseases. They produce symptoms attributable to obstruction at the right side of the heart, namely, dyspnœa and cyanosis, with notable smallness and feebleness of the pulse. These symptoms develop suddenly or more or less rapidly, and are generally the forerunners of speedy death. The heart-sounds are weakened, and it may be practicable to determine that the first sound is due to the tension of the mitral valve, without participation of the tricuspid valve. A tricuspid systolic murmur may be found which had not existed previously. Excluding pulmonary conditions which would account directly for the foregoing symptoms, and taking the latter in connection with physical signs, the diagnosis may sometimes be made with much positiveness.

Absolute rest, the sustaining measures of treatment, and the saturation of the blood with ammonia, constitute, with our present knowledge, the measures of treatment to be pursued. The history of some cases appears to show

[1] Zahn, Virchow's Archiv, Bd. 62, p. 81.

recovery, but there is always room for doubt, in these cases, respecting the diagnosis.

The fibrinous deposits upon vegetations or roughened spots, occurring generally within the left ventricle, are chiefly important from their liability to become detached and to give rise to emboli.

Embolism of the main trunk of the pulmonary artery may be here noticed as a cause of sudden or rapid death. The embolus may be derived from a thrombus formed within the right ventricle or auricle, or from a thrombus formed in a large vein, most frequently the femoral vein. The symptoms are sudden, urgent dyspnœa, not explicable by physical signs, cyanosis, coldness of the extremities, the pulse becoming rapidly small and feeble, and soon extinct.

Sudden and complete obstruction of one of the primary divisions of the pulmonary artery may take place without causing death or giving rise to permanent notable inconvenience, as was demonstrated in cases under my observation.[1]

CHAPTER V.

FUNCTIONAL DISORDER OF THE HEART.

Enlargement of the Thyroid Body and Prominence of the Eye-balls (Exophthalmic Goitre) associated with Functional Disorders of the Heart. Angina Pectoris. Thoracic Aneurism.

Functional Disorder.

BY the term functional disorder is meant disturbed action of the heart, not dependent on either inflammation or structural lesions. The beating of the heart is sometimes abnormally intense. The patient is conscious of its violent action, as when it is temporarily excited by fear or some other strong mental emotion. This is commonly known as palpitation. The sense of violence may be a subjective symptom only, the force of the heart's action not being actually increased; but generally the action is, at the same time, accelerated and irregular. The irregularity is represented by the pulse, and felt when the hand is placed over the præcordia. The patient is also painfully conscious of it; the organ appears sometimes to perform a rolling or tumbling movement, and a sensation is described as if the heart were in the throat. Intermittency of the heart's action is another feature in certain cases. The action of the heart is, for an instant, arrested; one, two, or three beats are lost, and generally irregularity of action precedes and follows the intermissions. Of these the patient is vividly sensible, and the feeling is that fatal suspension of the heart's action may be liable to take place. These rhythmical aberrations may be accompanied with either violent or feeble action of the heart. The varieties of functional disorder occur in paroxysms which are very variable as regards severity, frequency of occurrence, and duration. Excessive action of the heart, however, sometimes persists steadily for successive days, weeks, and months.

An occasional form of disorder is characterized by every alternate ven-

[1] *Vide* Clinical Medicine, by the Author, page 248.

tricular systole being so feeble as not to be appreciable by a radial pulse, the action of the heart being more or loss rapid. On auscultation the two heart-sounds are alternately loud and feeble. I have known this form of disorder to persist for several weeks.

This is liable to be mistaken for reduplication of the heart-sounds, there being four sounds to each radial pulse. The error is avoided by comparing the radial with the carotid pulse. The alternate feeble systoles are always strong enough to cause an appreciable pulsation of the carotids.

Reduplication of the heart-sounds denotes a variety of functional disorder, giving rise, however, to no definite subjective symptoms, and occurring in various pathological connections. Reduplication of both sounds may be appreciable, or it may be limited to one sound which is usually the second. The reduplication is recognized easily by one accustomed to auscultation, and the proof is the occurrence of three or four sounds for each carotid pulse. A slight deviation from synchronism in the contraction of the right and the left ventricle accounts satisfactorily for the reduplication of both sounds, but not so satisfactorily for a reduplication limited to the second sound. The latter is, perhaps, best explained by supposing that the contraction of the right ventricle, distinct from the left, has not sufficient force to produce an appreciable sound, especially as this disorder is apt to occur when the heart is weakened. It may be, however, that, under certain conditions of arterial pressure, the recoil of the aorta and of the pulmonary artery, after the ventricular systole, is not in unison. This will account for a reduplication of the second sound, although the systoles of the two ventricles occur synchronously.

A variety of functional disorder to which the attention of clinical observers has not been much directed is diminished frequency of the heart's action. In a paper on this topic, I have reported several cases in which the number of ventricular systoles was diminished to from 40 to 26 per minute.[1] Physical exploration in these cases showed that the disorder was not associated with any organic affection of the heart. The disorder was associated with more or less cerebral disturbance, but the evidence of intra-cranial inflammation, embolism, and hemorrhage was wanting, and in every instance the disorder was temporary. I have met with other examples since the publication of that paper. The cardiac disorder is evidently connected with some centric nervous condition which affects the heart through the inhibitory function of the pneumogastrics. To recognize the disorder as a functional one is important; otherwise it is regarded as a symptom pointing to some grave cerebral affection. It was so regarded in the cases which I have reported. Before deciding that the disorder exists, two points are to be ascertained, namely, *first*, that the radial beats represent accurately the ventricular systoles, that is, to distinguish this from another variety of functional disorder which has been noticed in which every alternate systole is too feeble to produce an appreciable pulse at the wrist; and, *second*, that the patient has not normally an infrequent pulse. The exclusion of grave cerebral affections by the absence of other evidences of their existence than the infrequent pulse, is, of course, important. The cerebral affections which diminish the frequency of the heart's action rarely, if ever, occasion so great an infrequency as occurs in some instances in which it is purely functional. As great, or greater, infrequency is observed in some cases of fatty degeneration of the heart; hence this lesion, as well as other organic affections, is to be excluded.

Infrequency of the heart's action, reduplication of the heart-sounds, and the disorder characterized by alternate systoles too feeble to be represented

[1] *Vide* the American Practitioner, January, 1876.

by a radial pulse, are rare varieties. The most frequent varieties are the forms of disturbance first mentioned, namely, rapid action either violent or fluttering, irregularity, and intermittency, occurring in paroxysms. They are often met with in practice. They usually give rise to great mental apprehension. The patient has a firm conviction of the existence of organic disease, and is in fear of sudden death. It is sometimes difficult to remove this conviction by the most positive assurances to the contrary. Cases of functional disorder are distinguished, as a rule, by much mental anxiety and depression, in this respect differing from cases in which disturbed action is due to structural lesions.

The causes of functional disorder are various. It sometimes occurs in so-called full-blooded persons addicted to the pleasures of the table, digesting and assimilating actively, and taking but little active exercise. It is much oftener, however, associated with anæmia. Anæmic persons are rarely exempt from more or less disturbance of the heart's action. It may be produced by long-continued mental anxiety or depression. It is apt to occur in persons of an anxious, worrying disposition, and in those who are constitutionally disposed to melancholy. The effect which it produces on the mind reacts on the disorder, and tends to perpetuate it. It appears, in some cases, to be dependent on indigestion or dyspepsia, and paroxysms are apt to be excited by dietetic errors. The immoderate use of tobacco gives rise to it in some persons; so, also, strong tea, and coffee. It is incidental to the gouty diathesis. The exhaustion following prolonged mental excitement and physical exertions may be accompanied by it. It prevailed to a great extent among soldiers during the late civil war, excessive and persistent palpitation often leading to discharge on the ground of disability from supposed organic disease of the heart. Excessive venery and habits of self-abuse are to be included among the causes. The associated symptoms will, of course, vary according to the different circumstances under which it occurs. The different causes, of course, act upon the nervous system; but it is not certain whether the particular nerves acted upon are the pneumogastrics, the sympathetic, or the nerves and ganglion-cells within the structure of the heart.

It is extremely desirable, in view of the comfort and welfare of the patient, to determine with positiveness, in cases of functional disorder, that structural lesions do not exist. Several points, connected with the history and symptoms, have a bearing on the diagnosis. The occurrence of the disturbance in paroxysms, the action at other times being regular; the paroxysms occurring at night rather than in the daytime, and frequently not being occasioned by any obvious cause, such as muscular exertion or mental excitement; the ability of the patient to take active exercise without palpitation or dyspnœa when not suffering from the disorder, and the intensity of mental anxiety and apprehension, are points which render it probable that the difficulty is purely functional. These points, however, are not conclusive. A positive diagnosis is to be based on the exclusion of lesions of structure by the absence of the physical signs of the latter. If, on a careful examination of the chest, the heart be found not to be enlarged; if there be no murmur present, or if an existing murmur be inorganic, and the heart-sounds be normal, the affection may be confidently pronounced functional. Without the negative proof afforded by physical exploration, the mind of the practitioner must be in doubt as to the diagnosis. If he give a decided opinion, it is a guess which may prove to be either right or wrong. If he avoid giving a decided opinion, the inference which the patient usually draws is, that organic disease exists, and that the physician is reluctant to tell the truth. I could cite, from cases which have come under my observation, not a few in which patients were for many years rendered unhappy and deterred from engaging in the active duties of life, by either an erroneous medical opinion

that they had organic disease of the heart, or by a fixed belief that such was the fact, based on the indecision of the physician.

The curative treatment of functional disorder must have reference to the circumstances with which it is connected. Occurring in connection with what is known as a "full habit," the measures indicated are, restriction of diet, exercise in the open air, depletion by saline laxatives and perhaps by small bloodlettings. Occurring in connection with anæmia, measures of precisely an opposite character are indicated, namely, those designed to restore the normal condition of the blood. An investigation with reference to the source of the disorder is to be made in all cases, and the causes, if apparent, are to be obviated. If connected with dyspeptic ailments, these are to be remedied by appropriate treatment; and if dependent on the gouty diathesis, this will claim suitable remedies. In the great majority of cases, the proper treatment consists of tonic remedies, a nutritious, regular diet, and an avoidance of excesses of all kinds; a proper amount of sleep, the interdiction of tobacco, strong coffee and tea, and out-door life with mental recreation—in short, an invigorating system of hygiene. Positive assurances of the absence of organic disease, such as may be given if based on the absence of all the physical signs of lesions, will often go far toward effecting a cure, the disorder being frequently kept up by mental inquietude occasioned by the fear of sudden death.

During the paroxysms palliative measures are called for. These consist of ethereal stimulants, anti-spasmodics, and occasionally opiates, with sinapisms or stimulating liniments to the chest. If paroxysms occur frequently, a belladonna plaster may be constantly worn over the præcordia. Blisters or other severe counter-irritants are never requisite. Small doses of aconite are useful if the action of the heart be violent, and, on the other hand, if the action be feeble and irregular, digitalis may prove of use. Kunze and other German authors recommend, as a palliative measure, wearing an ice-bag over the præcordia. A mouthful of brandy, or some other spirit, swallowed undiluted, will sometimes arrest promptly a paroxysm.

Some persons are strongly predisposed to disturbed action of the heart, and suffer more or less from paroxysms of functional disorder for many years, or during their whole lives. The mental anxiety in such cases after a time ceases, and patients become reconciled to this as to other physical evils. The frequent recurrence of functional disorder for an indefinite period does not lead to the development of organic disease. The physician is fully warranted in giving positive assurance to the patient on this point.

In the foregoing remarks on functional disorder, it has been assumed that structural lesions are not present. But functional disorder and lesions may be associated when the former is not dependent on the latter; in other words, the causes which give rise to functional disorder when the heart is free from lesions, will produce the same effect when cardiac lesions exist. It is highly important that the practitioner appreciate this fact. Not infrequently the disturbance of the heart's action in cases in which organic murmurs are found, is mainly or exclusively functional. It is not uncommon for practitioners to err in considering all the symptoms referable to the heart as arising from organic lesions, although these may be entirely innocuous. Anæmia co-existing with lesions, may occasion greatly disturbed action of the heart, with dyspnœa and even general dropsy, so that the patient may seem to be in the last stage of cardiac disease, and, if the anæmia be cured, the recovery sometimes appears to be complete. It should always, therefore, be a question, in cases of organic lesions, whether more or less of the symptomatic phenomena may not be due to functional disorder arising from anæmia, deranged digestion, or a morbid condition of the nervous system produced by tobacco, coffee or tea, mental depression, excessive venery, or gout. This question is to be

decided in the affirmative when causes of functional disorder are discoverable, and when the organic affection, as determined by the physical signs, appears to be insufficient to account for the symptomatic phenomena. In proportion as the latter are fairly attributable to functional disorder, the prognosis is, of course, less grave, and improvement may be expected from appropriate treatment.

Enlargement of the Thyroid Body and Prominence of the Eyeballs (Exophthalmic Goitre) associated with Functional Disorder of the Heart.

Within the last few years, the attention of clinical observers has been directed to an affection characterized by enlargement of the thyroid body and prominence of the eyeballs, conjoined with inordinate action of the heart. These three pathological events form a striking combination, giving to the affection a well-marked individuality. In the absence of a name expressive of its character, a German author, Hirsch, applied to it the name *Basedow's disease*, after a German observer who was among the first to describe it fully; and the distinguished clinical teacher, Trousseau, in view of the prior claim of the late Dr. Graves, proposed to call it *Graves' disease*. The three events just named evidently have some pathological connection, the nature of which is not yet fully established.

The prominence of the eyes is the most remarkable of the triple events. Existing, in some cases, in a marked degree, it gives to the countenance a peculiar expression. The projection of the globes displays more or less of the tunica albuginea, and the patient has a ferocious, staring look which, existing in both eyes, is at once diagnostic. The projection is sometimes so great as to prevent closure of the lids, and the eyeballs are partially exposed during sleep. Vision is generally not impaired, and the appearance of the eyes, aside from the prominence, is natural. The condition of the eyes does not involve pain, but the patient sometimes feels as if the eyeballs were being squeezed out of the sockets. Accompanying and sometimes preceding the exophthalmus, defective co-ordination of the movements of the eyeballs with those of the upper eyelids is observed. If the patient look downward, the eyeballs move without corresponding movements of the lids. This defective co-ordination is not a feature in all cases. The exophthalmus is sometimes more marked on one side, and it may be unilateral. Falling out of the eyebrows and ciliæ is sometimes observed. The thyroid body is more or less enlarged, the enlargement being usually greater on the right side. The increase does not go on indefinitely, forming the immense tumors which are sometimes seen in cases of ordinary bronchocele or goitre, but ceases after a moderate or considerable augmentation of bulk has been attained. The swelling does not give rise to pain, but it may occasion some obstruction to respiration from pressure on the trachea, and may lead to embarrassed breathing and modification of the voice by interfering with the function of the recurrent laryngeal nerve. The thyroid arteries are enlarged, and a strong pulsation is felt over these and the carotids, frequently accompanied by marked thrill. Arterial and venous murmurs, frequently loud and sometimes musical, are heard when the stethoscope is placed over and near the enlarged thyroid body. The degree of the thyroid enlargement is often variable at different times.

Increased action of the heart is a contant and notable feature. In some cases this amounts to a persisting palpitation. The pulse varies from 100 to 140 beats per minute. Valvular lesions and enlargement of the heart exist in some, but by no means in all, cases. When present, they do not account

for the functional disorder. Loud inorganic murmurs at the arterial orifices of the heart are not infrequent. The inordinate action of the heart may continue persistently for months and years.

More or less anæmia co-exists generally, but not invariably. This has been by some incorrectly considered as an essential pathological element of the affection. The anæmia, however, is usually marked. Other symptoms are, mental depression and irritability, insomnia, amenorrhœa, abnormal increase of the appetite followed by anorexia, hysterical phenomena and emaciation. The affection is essentially chronic. In the majority of cases it continues for years. It does not tend intrinsically to a fatal result, but patients are apt to be cut off during its continuance by some intercurrent affection. Recovery takes place in a certain proportion of cases, the improvement being slow, and some degree of enlargement of the thyroid body and prominence of the eyes often being permanent. Fothergill quotes from Von Dusch 14 complete recoveries in 56, and great improvement in 26, cases; and of cases observed by Von Graefe, the ratio of recoveries was 20, and of great improvement 30, per cent.

The affection is rare, and, since the attention of clinical observers has been directed to it only within the past few years, further materials for its clinical history are yet to be gathered. At the date of the publication of the fourth edition of this work (1873) I had notes of only seven cases. Of these seven cases one was a girl sixteen years of age. The affection was slight, and at the age of twenty-two she married. She died three years after her marriage, having been recently confined. One case was under my observation in the Bellevue and Charity Hospitals for eight years. Hypertrophy of the heart was developed in this case under my observation. The exophthalmic and thyroid enlargement disappeared. She declined in strength, progressively emaciated, and died by exhaustion. The heart weighed twenty ounces and the kidneys presented fibroid degeneration. In the third case the patient, a woman aged twenty-nine, was under my observation for three years, without any material change, except that the thyroid enlargement disappeared. The pulse was habitually 140. In the fourth case, a woman, aged forty, the disease had existed for ten years. Notable improvement had taken place in this case. She came under my observation in an attack of pneumonia which proved fatal apparently from heart-clot. In three cases the patients were only temporarily under my observation, and the subsequent history was not ascertained. Since 1873 I have probably seen as many cases as prior to that date, but I have histories of only two. In one of these complete recovery has taken place. The other case has been under my observation for three years, and the improvement is such as to amount nearly to recovery.

The pathological character of the affection is not established. That the three pathological events are due exclusively to anæmia is disproved by the occurrence of anæmia so frequently without these events, and by the fact that there is not always co-existing anæmia. The enlargement of the thyroid body is chiefly due to enlarged vessels. The prominence of the eyes is not due to enlargement of the globes. In autopsical examinations which have been reported, an abnormal amount of areolar and adipose tissue has been found at the bottom of the orbit. But that the protrusion is not chiefly due to this cause is shown by the fact that it has been observed to cease after death; and during life moderate pressure suffices to restore the globes to their normal situation. Enlargement of the vessels behind the globes is probably the chief cause. The prominence of the eyes and enlargement of the thyroid body are consecutive to the cardiac disorder. Cases are observed in which enlargement of the thyroid body is conjoined with inordinate functional activity of the heart, without prominence of the eyes, and the two latter may be asso-

ciated without enlargement of the thyroid body. Examples of each of these variations have fallen under my observation. I have met with cases of rapid action of the heart persisting for a long period without either prominence of the eyes or enlargement of the thyroid bodies, in which I suppose the affection to be the same *minus* these associated events. Considering that the cardiac disturbance always precedes the two other characteristic events, that either of the latter may be wanting, and that both involve enlargement of vessels, a fundamental morbid condition evidently relates to the circulatory system. But this condition probably involves a prior neuropathic affection which, it is probable, pertains to the sympathetic nerve. In some instances morbid appearances after death in and around the cervical sympathetic nerve have been found, but in other instances nothing was discoverable. The neuropathic condition is supposed, by some, to be seated in either the cervical portion of the spinal cord or the medulla oblongata. The affection, in the great majority of cases, occurs in females. Of fifty cases collected by Wilthuisen, a Danish author, only eight were male subjects. In all the cases which I have seen, save one, the patients were females.

The indications for treatment relate to the functional disorder of the heart, together with the morbid state of the nervous system and the often co-existing anæmia. Sedative remedies which tranquillize the action of the heart without producing depression or interfering with the appetite and digestion, are indicated. For this end, hydrocyanic acid, aconite, belladonna, and digitalis may be employed. The anæmia calls for tonic remedies, and especially ferruginous tonics; the latter have seemed to be beneficial in cases which I have observed. Arsenic has been found useful, but in some instances has apparently done harm. Iodine, with reference to the affection of the thyroid body, is of doubtful utility. In the two cases to which reference has been made as occurring since 1873, the recovery in the one case and the notable improvement in the other case, were under the use of the tincture of aconite. In the first of these cases the patient took one minim only of the tincture three times daily, but continued it for three years, in conjunction with a chalybeate tonic. At the end of that period she was perfectly well, and had increased in weight forty pounds. In the other case the dose of the tincture was gradually increased to seven minims, three times daily, and continued steadily for ten months, without a chalybeate, anæmia not existing in this case. Several observers bear testimony to the usefulness of galvanization, with the constant current, of the cervical sympathetic nerves. Cases of recovery under this agent have been reported. Ergot is among the remedies which have been found of service. Hygienic measures are of much importance in the treatment. Freedom from mental depression is to be secured as far as possible, and, whenever practicable, change of scene and other means of mental recreation are advisable. The diet should be nutritious, and out-door life is desirable. Trousseau advocated the employment of cold water after the hydropathic method.

Angina Pectoris.

The affection known as angina pectoris involves, as an essential feature, neuralgia, and might, therefore, be included among the diseases of the nervous system. It is considered here on account of its frequent connection with cardiac lesions and with notable disorder of the heart's action. The following description will relate to typical cases of angina associated with disease of the heart.

The affection is characterized by pain, usually intense, burning, tearing, or lancinating in character, emanating from the præcordia or beneath the ster-

num, and radiating thence in different directions, namely, into both sides of the chest, the back, and frequently the left shoulder; extending down the arm and sometimes to the forearm; occasionally felt in the forearm and hand and not in the shoulder and arm; in some cases extending more or less into both upper extremities, and it has been known to extend into one or both of the lower extremities; and, finally, it may shoot upward into the neck, temples, and jaws. Different cases differ much as regards the intensity of the pain and the situations, among those just named, in which it is felt. The pain in some cases is so intense as to be truly excruciating, and is accompanied by a feeling of constriction of the chest; in other cases it is moderate, or even comparatively slight.

The affection is paroxysmal, and the pain is but one of the elements which enter into the paroxysm. The action of the heart is generally more or less disturbed. The beats are irregular, sometimes violent or tumultuous, and sometimes feeble. In some cases the pulse is notably slow. An indescribable anguish or "heart-pang" is another element. A vivid sense of impending death is felt. The paroxysm is usually developed suddenly, and the patient feels compelled instantly to remain perfectly still, seizing hold of some firm support in order to maintain a fixed position. The patient is afraid to breathe freely, although the power of doing so is not lost. Dyspnœa does not belong to the paroxysms save in so far as it may depend on existing cardiac lesions, or on the voluntary restraint of the respiratory movements. A sense of numbness is felt in the parts into which the pain extends. The countenance denotes anxiety and suffering. The surface is generally pallid, cool or cold, frequently bathed in perspiration, and sometimes cyanosed or livid.

Cases differ greatly as regards, not only the severity of the paroxysms, but their duration and the frequency of their recurrence. They usually last for a few moments only, but in some cases they continue for several hours. They may recur at wide intervals or frequently. As a rule, to which there are a few exceptions, if a paroxysm have been once experienced, other paroxysms will follow sooner or later. Generally they become progressively more and more frequent. At first, and for some time, they appear to be excited by some notable cause, such as unusual muscular exertion or mental emotion; but after a time, they are liable to occur from trivial causes and without any apparent cause. They are sometimes produced during sleep apparently by distressing dreams.

The affection, as thus described, is incidental generally to organic disease of the heart or of the aorta, but, as far as at present known, not with any one form of lesion. It is much oftener associated with lesions at the aortic than at the mitral orifice, yet it occurs in only a very small proportion of the cases of aortic lesions. It occurs in some cases of fatty degeneration of the heart without valvular lesions. It is sometimes associated with aneurism of the aorta. It has been observed in cases in which the coronary arteries are obstructed by calcification or other lesions, but obstruction of these arteries is not essential to its occurrence, as was at one time supposed. The affection is rare. Of over 150 cases of organic disease of the heart which I analyzed in 1859, it occurred in only 7; and it occurred in 8 out of 188 additional cases analyzed in 1869. That it has a pathological connection with organic disease of the heart is certain, but upon what particular condition or circumstance common to different forms of organic disease it depends, is not ascertained.

Angina pectoris, especially if associated with diseases of the heart, involves liability to sudden death. Death takes place suddenly in a paroxysm. The most reasonable way of accounting for the sudden death, as it seems to me, is to attribute it to over-accumulation of blood within the ventricular cavities, and arrest of the heart's action as a result of paralysis from distension. The

explanation, in fact, is the same as of sudden death in cases of free aortic regurgitation, and fatty degeneration. The liability to sudden death characterizes cases in which the co-existing organic disease is of a kind to favor sudden over-accumulation of blood in the cavities. Aortic lesions and fatty degeneration have this effect. If the lesions do not lead to this effect, patients rarely die suddenly, but linger on for an indefinite period with the recurrence of the paroxysms more or less frequently. Moreover, the overloading of the cavities of the heart will account for elements of the paroxysms other than the pain, namely, the disturbed action of the heart, the indescribable anguish, and the sense of impending death. If the lesions to which the angina is incidental be not of a character to lead to overloading and consequent distension of the ventricular walls, the suffering is mainly from the pain. Some cases of angina are of this description, very little disturbance of the heart's action accompanying the paroxysm. On the other hand, all the elements of a paroxysm of angina, except the pain, are observed, not infrequently, in cases of aortic lesions with regurgitation; and sudden death is liable to occur in the paroxysms of distress to which patients affected with these lesions are subject, the paroxysm lacking only pain to constitute angina pectoris. The prognosis in cases of angina is always grave if physical signs show the existence of serious cardiac lesions; and sudden death is to be expected if there be much aortic regurgitation, or the habitual weakness of the heart render probable fatty degeneration or impaired nutrition of the organ. The danger, it is to be observed, is not to be measured by the intensity of the pain; it is not the pain which kills, but the co-existing organic disease.

Angina pectoris, as far as the neuralgic element is concerned, may occur without any evidence of co-existing disease of the heart or the aorta. Several examples have fallen under my observation. In these cases the paroxysms generally lack those elements which are derived from cardiac lesions. The necessity of keeping a fixed posture while the paroxysm lasts, is not felt in the same degree; the patient may writhe with pain, and try frequent changes of posture with the hope of obtaining relief. The sense of impending death is less, or may be wanting. There is less danger of sudden death, and the prognosis as regards recovery is favorable. These points are to be considered in the differentiation of these cases from those in which the angina is connected with disease of the heart; but the absence of cardiac lesions is determined by the negative result of a careful physical exploration of the chest. It is, however, to be considered that there are anatomical changes not represented by physical signs, *e. g.*, defective nutrition from obstruction of the coronary arteries. It may be stated that the danger in a given paroxysm is in proportion to the feebleness and irregularity of the heart's action, together with a feeling of impending dissolution. In the endeavor to estimate the danger, the nature and extent of lesions, as evidenced by signs, are to be taken into account. Much damage of the aortic valves, dilatation of the left ventricle, and weakness of the heart from fatty degeneration or innutrition, are the conditions which especially render paroxysms dangerous. Yet, there are cases in which the paroxysms recur for a long time without proving fatal, although heart lesions exist, and if the latter do not exist, it is probably true that there is little danger of sudden death. I have reported several instances of recovery in the second edition of my work on Diseases of the Heart (1869); such instances should not be lost sight of in the prognosis. Angina is to be discriminated from intercostal neuralgia and gastralgia. Each of these affections I have known to be mistaken for it. Paroxysms of intercostal neuralgia are sometimes so severe as to rival, in the intensity of pain, attacks of angina. In other respects the points of distinction are sufficiently marked. Both

intercostal neuralgia and gastralgia are distinguished by their own diagnostic traits, aside from the absence of those which belong to angina.

Pertaining to the pathological character and relations of the different elements in angina, are discussions which cannot be here entered into. The neuralgic element, probably, has its primary seat in the cardiac plexuses, and the radiation of pain to the neck and upper extremities, as well as other parts of the chest, may be explained by anatomical connections with branches of the cervical and dorsal nerves. As remarked by Eulenberg, the pain closely resembles that referable to the sympathetic nerve in other situations, for examples, hepatic colic, enteralgia, etc. The disturbed action of the heart, irrespective of cardiac lesions, is as unintelligible as when it occurs in the various forms of functional disorder. The increase of blood pressure from arterial spasm referable to the vaso-motor system, may be a pathological element in some cases. To institute several varieties of the disease, according to the different nerves supposed to be involved, seems to me to be, in the present state of our knowledge premature and confusing. Practically, however, the presence or absence of cardiac lesions, and the degree of disturbance of the heart's action in the paroxysms, are important points, especially in reference to prognosis, and the liability to sudden death.

The treatment embraces measures to afford relief in the paroxysms, and those indicated in the intervals. The palliative measures embrace opium, given promptly and sufficiently to relieve the pain. It should be given in a form to act as speedily as possible. The hypodermic method, if the physician happen to be at hand, is to be preferred. Alcoholic, ethereal, and other stimulants are indicated in proportion as the action of the heart is irregular and feeble. Revulsive applications to the chest and extremities are appropriate. Swallowing pieces of ice has been found effective. The nitrite of amyl is a valuable remedy. Five drops inhaled from a handkerchief held over the nostrils will often arrest almost instantly a paroxysm. It may prevent sudden death, and trial of it should therefore always be made, observing, of course, proper precautions in its use. This remedy relieves by inducing relaxation of the bloodvessels and a consequent diminution of blood pressure. Its efficacy is consistent with the theory which attributes the angina to arterial spasm, but the theory is by no means thereby established. The remedy is efficacious in only a certain proportion of cases. Naturally, its efficacy is most marked when there is much arterial tension, but it may relieve, although this element be wanting, by diminishing the accumulation of blood in the heart-centres. The inhalation of ether or of chloroform is to be enumerated among the resources for arresting the pain, or mitigating its severity. The inhalation of chloroform should not be resorted to if the action of the heart be feeble.

In the intervals, the patient should avoid, as far as possible, everything which will be likely to provoke a paroxysm, such as active exercise, mental excitement, over-ingestion of food, and the abuse of alcohol. Aside from prophylaxis, the measures indicated are those which have reference to the causes of neuralgia, to the general health, and, in the majority of cases, to co-existing organic disease of the heart or the aorta. Anstie found arsenic, in small doses long continued, extremely useful in preventing the paroxysms. Others have recommended this remedy, and, again, others have seen no benefit from it. A fair inference is that it is sometimes useful and sometimes not, as in other neuralgic affections. Trousseau, who regarded the affection as analogous to epileptic seizures, and called it *cardiac epilepsy*, advised the long-continued employment of belladonna. Electrization of the surface within the præcordia has been found useful both in arresting the paroxysms and postponing their occurrence. The cases most likely to be amenable to treatment

are those in which the angina is purely neuralgic, that is, not associated with heart-lesions.

The name angina is singularly inappropriate as applied to this disease, inasmuch as neither the symptoms nor the danger have aught to do with strangulation. The term stenocardia has significance only as denoting a sensation, accompanying the pain. Of the other various names, most imply erroneous views of the nature of the malady. Cardialgia would be an appropriate name had it not been applied to a gastric affection.

Thoracic Aneurism.

An atheromatous condition of the arteries has been usually assigned as the leading cause of spontaneous aneurisms. This atheromatous process is at the onset inflammatory; it is an endarteritis chronica deformans (Virchow). The intima at first is swollen and of a whitish or gelatinous appearance in patches. In these swollen patches are round, fusiform, and stellate cells in increased number; the intercellular substance is imperfectly fibrillated; the endothelial lining of the vessel is preserved. Subsequently, fatty and calcareous degenerations occur in the cells and intercellular substance; to the resulting pulpy mass, often containing cholesterine, the name atheromatous abscess has been inappropriately applied. This mass may be discharged by rupture of the endothelial covering. An atheromatous ulcer is the result. Recent investigations have rendered it probable that undue importance has been assigned to atheroma as a cause of aneurism. Atheroma is most frequent in old age, a period of life in which aneurisms are by no means most common. The view is now held that the most frequent cause of spontaneous sacculated aneurisms is to be sought in changes in the middle or muscular coat of an artery. According to Helmstedter, these aneurisms result from rupture of the elastic fibres of the media in consequence of a primary or secondary molecular alteration of these fibres. Köster believes that the primary change is a localized inflammation of the middle coat—a mesarteritis—in the neighborhood of the vasa vasorum. This inflammation causes destruction of the muscular fibres and weakening of the arterial coats. Atheroma remains as a cause of diffuse cylindrical aneurisms, nor can its influence be wholly ignored in the production of other aneurisms.

Referring the reader to other works for a fuller account of aneurisms, as regards their pathology and morbid anatomy, I shall consider, in this article, aneurismal tumors of the thoracic aorta, with reference to their symptoms, physical signs, prognosis, and treatment. As bearing on the diagnosis, it may be here stated that aortic aneurism is a rare event under forty years of age, and that syphilis is often a remote cause.

Aneurismal tumors may spring from the thoracic aorta at different points. Not infrequently they originate within the pericardium, in the sinuses of Valsalva, and, in this situation, rupture takes place before the tumor attains to great size, the hemorrhage taking place into the pericardial sac, and, of course, causing instant or very speedy death. A fatal result from aneurism in this situation may occur without having been preceded by any symptoms of importance; death takes place unexpectedly, perhaps when the health was apparently perfect. The diagnosis is difficult and perhaps impossible. Of 703 cases analyzed by Sibson (*Med. Anatomy*, fasc. v.), 87 were within the pericardium. The ascending portion of the arch without the pericardium is the most frequent site; in 193 of the 703 cases analyzed by Sibson, the situation was in this portion. The ascending and transverse portions are not

infrequently both involved in the dilatation. This was the case in 140 of 703 cases. The transverse portion was affected alone in 120 cases, and, conjointly with the descending aorta, in 20 cases. The descending portion of the arch was the seat in 72, and the aorta below the arch in 71 cases. The aneurismal tumors in the larger proportion of cases spring from the outer aspect of the artery, but they may spring from either the inner, posterior, or anterior aspect.

Aneurismal tumors, according to their situation and size, give rise to certain symptoms and signs by pressing upon the different surrounding parts. Unless referred to their true source, these symptoms may mislead the physician by appearing to indicate other affections. And by means of these symptoms and signs, not only may aneurism be suspected, but, assuming its existence, its situation may be inferred.

Interruption of the circulation through the innominata and the left carotid and subclavian artery may arise either from the pressure of the tumor on these vessels or obstruction by fibrinous plugs. Feebleness or extinction of the pulse in the radial, brachial, or carotid artery on one side is one of the symptoms of aneurism, and indicates its situation to be at the right or left extremity of the transverse portion of the arch. When the radial pulse is not abolished, but more or less weakened, the contrast between the pulse of the two arms is well shown by a comparison of the visible characters as traced by the sphygmograph. A notable retardation of arterial pulsations beyond the seat of the aneurism is sometimes observed. Thus, when the aneurism is seated between the points of origin of the great vessels of the arch of the aorta, the radial pulse is felt later on one side than on the other; and, if the aneurism be seated in the descending aorta, the pulsations of the arteries below occur later than the pulse at the wrist. An aneurismal tumor springing from the ascending or transverse portion of the arch may press upon the superior vena cava or the venæ innominatæ, and induce venous congestion limited to the head and upper extremities, or to one upper extremity, accompanied, perhaps, by more or less œdema. These symptoms point to the existence and situation of aneurism.

An aneurism seated in the transverse portion of the arch may press upon the trachea or one of the primary bronchi, and interfere with respiration. If the obstruction of the trachea be considerable, the breathing is labored, and may be accompanied with a noise, heard at a distance, called stridor. Auscultation will show feebleness of the respiratory murmur on both sides of the chest if the trachea be pressed upon, but feebleness limited to one side, and the murmur exaggerated on the other side, if one of the bronchi be obstructed. Embarrassment of respiration may proceed from pressure upon the recurrent laryngeal nerve. If the pressure be sufficient to interrupt the function of the nerve on one side, laryngeal obstruction arises from an arrest of the respiratory movements of the glottis on that side. The embarrassment from this cause, however, is not great. The laryngoscope in these cases shows the vocal cord on one side to be paralyzed, while the respiratory movements of the other cord continue, or, after a time, the paralysis may become bilateral. Spasm of the glottis may be induced if the relation of the nerve to the tumor be such that it is irritated instead of its function being annulled. I have reported a case in which, the left recurrent nerve being situated between a calcareous deposit and the aneurismal tumor, spasm of the glottis occurred so frequently and to such an extent as to prove fatal.[1] Dysphonia and aphonia are effects of either incomplete or complete paralysis from pressure on the recurrent laryngeal nerve, and the affection of the voice is

[1] American Medical Times, 1864.

found to vary at different times according to the varying amount of pressure. These laryngeal symptoms are apt to mislead by directing attention to the larynx as the seat of disease. Tracheotomy has been repeatedly performed under the belief that the obstruction of respiration was due to an affection of the larynx. Pressure of the tumor on the pneumogastric nerve, as ascertained after death, occasioned vomiting and pyrosis in a case reported to me by Prof. McCready.

Pressure on the œsophagus, when the tumor is situated in the transverse or descending aorta, may occasion obstruction to the passage of food. This symptom should excite suspicion of aneurism, and such a suspicion should enforce caution in the use of bougies to explore and dilate the œsophagus. Pressure on the thoracic duct has been known to occur, inducing marked emaciation. Pressure on the sympathetic nerve is another effect of an aneurismal tumor, leading to contraction of the pupil of the eye on the affected side. If the tumor be seated in the descending aorta, it is likely to lead to erosion of the vertebral column, and may thus occasion paralysis by affecting the spinal cord. These cases are characterized by considerable pain referred to the back. Neuralgic pains and well-marked angina pectoris sometimes accompany aneurism seated in the ascending aorta.

The diagnosis of thoracic aneurism is to be based on the presence of more or less of the foregoing symptomatic phenomena, taken in connection with the physical signs of a tumor within the chest, situated at some point in the tract of the aorta. The signs are very obvious when the aneurism has led to erosion of the ribs and an external tumor, the latter pulsating, perhaps presenting a thrill, the heart-sounds heard with more or less intensity when the stethoscope is placed over it, together with a single or double bellows murmur. The signs are less marked before the tumor makes its way through the thoracic wall, but they may be sufficient to render the diagnosis positive. Abnormal dulness on percussion over a circumscribed space in the tract of the aorta, is an important diagnostic point. This space will be on the anterior surface of the chest, if the aneurism spring from the arch, and posteriorly if it spring from the descending aorta below the arch. Careful inspection and palpation may disclose pulsation and perhaps thrill before any external tumor is apparent. Undue audibleness of the heart-sounds within the space found to be dull on percussion, and a single or double murmur not transmitted from the aortic orifice, are highly significant signs. They are, however, by no means uniformly present, and, therefore, while their presence contributes to the diagnosis, their absence is not proof that aneurism does not exist.

The prognosis, in cases of thoracic aneurism, relates chiefly to the duration of life. The instances of recovery are few. In the majority of cases, death is the result of rupture of the aneurismal sac. The rupture may take place in various directions, namely, externally, or into the œsophagus, trachea, bronchi, pleural cavity, heart, venæ cavæ, spinal canal, pericardial cavity, etc. The rupture may be at first small, so that death takes place more or less gradually; or it may be large enough to cause a sufficient hemorrhage to destroy life within a few moments. I have met with a case in which, after a considerable hemorrhage caused by rupture into a bronchus, the opening closed and a fatal recurrence of the hemorrhage did not take place until after several weeks, the patient, in the mean time, taking considerable exercise under the advice of a practitioner who scouted the idea of aneurism. The progress of the aneurism varies much in different cases, the duration of life being in some cases but a few months, and in some cases several years. In a considerable number of cases life is destroyed before rupture takes place. Pressure on the trachea, œsophagus, vena cava, thoracic duct, or irritation of the recurrent laryngeal nerve, may lead to a fatal result, or

the patient may be cut off by some intercurrent affection. Organic lesions of the heart co-exist in a certain proportion of cases. These, of course, involve distress and danger in proportion to their nature and extent, and may prove the immediate cause of death. Clinical observation shows that patients affected with thoracic aneurism rarely have pulmonary tuberculosis.

Recovery from thoracic aneurism sometimes takes place, but, in general, the only results to be hoped for from treatment are palliation of suffering and prolongation of life. With reference to these results, all active exertions are to be avoided, and, as far as possible, emotional excitement. The body is to be well nourished, if possible, but the diet should be unstimulating, and alcoholic stimulants interdicted. Liquids should be taken sparingly. The action of the heart, if abnormally strong, is to be diminished by sedative remedies, and perhaps, if the patient be full-blooded, in some cases, by small abstractions of blood. It is highly important not to impoverish the blood, and anæmia, if it exist, calls for the treatment appropriate to that condition. Pain and other incidental symptoms are to be palliated by appropriate remedies. If spasm of the glottis be induced, through the recurrent laryngeal nerve, to such a degree as to endanger life, laryngotomy is warrantable, if not advisable, with a view to palliation and the prolongation of life. This operation will, of course, be of no avail if the obstruction be due to pressure of the aneurismal tumor on the trachea.

The progress of the aneurism is retarded by the deposit of successive layers of fibrin within the aneurismal sac. It is in this mode that a cure sometimes takes place. It is desirable, therefore, that the blood should be rich in fibrin, and it is probable that the deposit is more likely to take place in proportion as the action of the heart is slow. Cardiac sedatives, namely, aconite, digitalis, and the veratrum viride, may in this way be useful. Certain remedies have a more direct curative effect in some cases of aneurism. At the present time, the iodide of potassium is to be relied upon more than any other known remedy. Cases in which a cure was apparently effected by this remedy have been reported by Roberts, Balfour, Bouillaud, and others. I have witnessed remarkable improvement under the use of this remedy in several cases.[1] The doses should be increased up to a point of comfortable tolerance and continued for a considerable period. The iodide of potassium should be faithfully tried in all cases of thoracic aneurism.

SECTION THIRD.

DISEASES AFFECTING THE HÆMATOPOIETIC SYSTEM.

CHAPTER I.

SIMPLE ANÆMIA. CHLOROSIS.

Introductory Remarks—Simple or Benign Anæmia—Chlorosis.

IN this section will be considered certain diseases which are believed to be the result of disturbances in the blood-forming functions. It is, therefore, proper to refer these diseases to the hæmatopoietic[1] (or blood-forming) system. As the constituents of the blood-plasma are derived more or less directly from the ingesta, we understand by the hæmatopoietic system especially those organs and parts in which resides the function of producing the formed constituents of the blood, namely, the red and the white corpuscles. The name cytogenic organs has also been employed in the same sense. Our knowledge as to the development of the blood-corpuscles and as to the situations in which they are formed, is very imperfect, notwithstanding the abundant researches devoted to these subjects, especially during the last few years. The parts to which has been assigned, with more or less probability, the function of forming blood-corpuscles after birth, are the lymphatic glands, the spleen, the red marrow of the bones, and the blood itself.[2] To these parts, therefore, may be given, at least provisionally, the name hæmatopoietic system.

The diseases of this section are grouped together, not so much with refer-

[1] From *αἷμα blood*, and *ποιέω to make*.

[2] Red marrow exists in all of the bones of embryos and young infants. In the long bones of adults it is replaced by yellow or fatty marrow. In severe forms of anæmia the yellow marrow is often transformed into red or embryonic marrow. The white corpuscles are believed to be derived from the lymph-glands and spleen, and, perhaps, from the red marrow which presents a structure similar to that of these organs. As to the origin of the red corpuscles, there are two opposing theories at present under discussion. The one, advocated especially by Hayem and by Pouchet, is, that the red corpuscles are formed from small, at first colorless, afterward colored, granules or corpuscles derived from the lymph, present in the blood at all times, most abundant after menstruation, severe hemorrhages, and, in general, in conditions characterized by rapid renewal of the blood-corpuscles. These bodies, called by Hayem hæmatoblasts, correspond, at least in part, to bodies previously designated as elementary granules and microcytes. The other theory, advocated by Neumann, Bizzozero, Rindfleisch, Osler, holds, as developing forms, the so-called nucleated red corpuscles present in considerable number in the marrow of the bones, and, probably, in the spleen, after hemorrhages and in severe anæmia from other causes. They have been found only exceptionally in the blood, but, according to Ehrlich, similar forms can be demonstrated there by particular methods of preparation. Most of the advocates of this theory regard them as transitional forms between white and red corpuscles. The chief argument for this hypothesis, is that similar nucleated red corpuscles precede in the embryo the appearance of the non-nucleated corpuscles, such as exist in the blood after birth. (*Vide* Rindfleisch, Archiv f. mikr. Anat., Bd. xvii. 1879, and Hayem, Archives de Physiol. norm. et path., 1878–9.)

ence to the anatomical parts affected, as in consequence of certain common characteristics. In the majority of these affections, we cannot explain, by known anatomical changes, the alteration which exists in the composition of the blood. This is true in spite of the fact that in many cases pathological changes have been recognized in parts thought to belong to the hæmatopoietic system. It is probable that often a relation of cause and effect exists between these changes and the blood alterations, but the connection is rendered obscure by our ignorance as to the life-history of the blood. The anatomical changes found in some of the diseases of this section, are to be regarded as secondary, rather than as primary, elements in the disease. We must content ourselves frequently with establishing the existence of some disturbance in the blood-forming function, without attempting to refer the disturbance to anatomical changes.

A common and distinctive characteristic of the diseases of this section, is the presence of anæmia, usually of a grave form. This anæmia is called *essential*, in that it is not referable to diseases which interfere secondarily with the composition of the blood, such as Bright's disease, cancer, phthisis, but is attributable to a direct interference with the blood-forming or blood-destroying functions. In many of the essential anæmias, no anatomical change has been found in the body which can, with any probability, be assigned as the cause of the anæmia; in others, as in leucocythæmia and pseudo-leucocythæmia there are morbid changes which may be considered as interfering more or less directly with the formation of the blood-corpuscles. In the diseases of this section the proportion between the consumption and the renewal of the corpuscular elements of the blood is disturbed. The destruction of the corpuscles may be abnormally increased (hæmophthisis), or the reproduction of corpuscles may be diminished below the normal amount (anæmatosis), or both conditions may be combined. It is usually impossible to determine in a given case which of these causes is at work. The result of this disproportion between consumption and renewal, is impoverishment of the blood or anæmia which, together with the consequent disturbance of nutrition, forms the dominating factor in all of these diseases. It will be found, therefore, that these affections have much in common in their clinical history. They are for the most part insidious in their onset and chronic in their course. As a rule, their causes are obscure, and, with the exception of simple anæmia and chlorosis, their prognosis is grave.

For certain general considerations concerning anæmia and the changes in anæmic blood the reader is referred to Part First (p. 62).

Simple or Benign Anæmia.

The names simple and benign may be used to designate anæmia when not pernicious nor an element of the other affections embraced in this section, and when the diseases, more or less general, of which the anæmic condition is symptomatic, such as phthisis, empyema, carcinoma, etc., may also be excluded. It may be said that, as thus restricted, anæmia is only a symptom. It occurs, however, under various circumstances, and, for convenience, it may be considered in the light of an individual disease with as much propriety as certain other events which are symptoms, for example, jaundice. Simple or benign anæmia, as just defined, enters largely into medical practice.

General anæmia, as regards anatomical distinctions (oligæmia, oligocythæmia, etc.), together with its causation and effects, has been considered in Part I. (*vide* page 62). The obvious causes are, *first*, loss of blood or hemorrhages; *second*, defective assimilation; and *third*, expenditure of certain blood-constituents, as in lactation and pregnancy. Hemorrhages, of course,

occur under a great variety of circumstances. In women, menorrhagia and flooding with labor are frequent causes. Defective assimilation may depend on a lack of food in sufficient quantity or of food sufficiently nutritious. And, with abundant alimentation, the processes of digestion may be so impaired as to prevent proper assimilation. Lactation and pregnancy are frequent causes. To these causes may be added certain toxical agencies which interfere with hæmatopoiesis, namely, lead, malaria, etc. Simple or benign anæmia is a sequel of diseases which have kept in abeyance either alimentation or assimilation. Women become anæmic much oftener than men, irrespective of the causes which are peculiar to the sex, namely, pregnancy, lactation and menorrhagia.

Anæmia gives rise to a multiplicity of morbid phenomena representing especially disorder of the nervous system. The more frequent and prominent are as follows: mental depression, anxiety respecting health, irritability of mind, want of buoyancy and energy, a feeling of lassitude, and a painful sense of inertia or indolence. There is apt to be a feeling of incapacity for muscular exertion greater than the actual loss of muscular power. The physical and mental powers are especially depressed during digestion. Palpitation of the heart is frequent, and organic disease is greatly feared by the patient. Neuralgia in various situations is apt to occur, and, in women, hyperæsthesia of the abdominal walls, simulating peritonitis. The varied symptoms formerly and recently described as due to spinal irritation, are liable to occur in connection with anæmia. The varied phenomena considered as hysterical are often associated with, and more or less dependent upon, anæmia. The special relations between the red corpuscles and the nervous system, are shown by the neuropathic phenomena to which anæmia gives rise. These phenomena may be said to constitute the pathological expressions of this morbid condition of the blood. The different organs of the body, in cases of anæmia, are deficient in functional power in proportion to the quantity of blood which they receive in health. The surface of the body is cool, and the extremities are apt to be cold. The ability to endure cold is lessened. There is diminished endurance of muscular, as well as mental, exertions. Generally, the face, especially the prolabia, and the mucous membrane in situations where it can be seen, are pallid. The facies often at once denotes anæmia. In some persons, however, the anæmic condition, as determined by physical signs and its pathological phenomena, exists, not only without pallor, but with even a rosy complexion. Pallor of the prolabia may be noticeable in the morning or if the patient be fatigued, and it may disappear under excitement. The action of the heart is feeble and easily disturbed, becoming rapid from slight causes. The respirations are panting on exercise. Digestion is labored. The urine often has a low specific gravity, from a deficiency of urea, and is notably limpid from a diminution of pigment. The cerulean eye, that is, a dark-blue tint of the globe, owing to a semi-transparency of the conjunctiva, may be a more marked feature than pallor of the face or the prolabia.

The symptomatic evidence generally renders the recognition of anæmia easy. Certain auscultatory signs confirm the diagnosis. The continuous murmur in the neck, known as the *venous hum*, is rarely wanting, and is not often present if there be not anæmia. A frequent sign is a systolic bellows murmur, referable to the carotid arteries. Not less frequently, systolic murmurs are heard at the base of the heart, produced within the aorta and the pulmonary artery. The significance of these murmurs depends on their hæmic origin, and this is rendered evident by the absence of signs denoting lesions of the heart or arteries. These hæmic murmurs are useful, not only in the diagnosis of anæmia, but as criteria by which the physician is aided in deciding whether the anæmic condition continues, or whether it has been

removed by measures of treatment. The diagnosis may be rendered demonstrative by ascertaining the number of red-corpuscles and the amount of hæmoglobin.

In order to decide that the anæmia is simple or benign, the pernicious form, leucocythæmia and pseudo-leucocythæmia—diseases considered in this section—are to be excluded, and, also, all other important diseases which involve, as a symptom or an effect, the anæmic condition. To exclude these diseases is generally not difficult. Although, as has been seen, anæmia stands in a causative relation to a large number and a great variety of pathological phenomena, there are not present symptoms which denote a grave condition. Pyrexia is wanting, and the general nutrition of the body may be well maintained. With reference to the exclusion of important diseases, it is necessary that the physician be qualified to appreciate the phenomena referable to the anæmia. In most instances the causes of the anæmia are apparent, and their existence is to be taken into account in the diagnosis. Moreover, the diagnosis is often corroborated by the speedy effect of appropriate treatment.

The prognosis, in cases of simple or benign anæmia, is generally good. Provided the causes do not continue in operation, recovery may be expected. Different cases differ much as regards the rapidity of progress toward recovery. In the exceptional cases which are treated unsuccessfully, there is reason to conclude that the want of success may be due to an innate defect in the hæmatopoietic system.

Anæmia may be associated with other diseases, the latter occurring in persons already anæmic. It is of great importance in practice to take cognizance of this association. The phenomena of the associated diseases are modified by the antecedent and co-existing anæmia. Toleration of diseases and recuperation are thereby impaired. Whatever may be the disease thus co-existing with anæmia, but without involving necessarily any relation of cause or effect, the anæmic condition claims recognition, and is to be considered in connection with the indications for treatment. With the different functional affections of the nervous system, anæmia is associated as a rule, standing often to them, measurably, in a causative relation. Clinical observation does not afford proof of its predisposing to phthisis, but rather the reverse.

In the treatment of anæmia, causal indications are of primary importance. The causes, in individual cases, are to be ascertained and, if possible, removed. Hemorrhages are to be arrested or restrained. Alimentary supplies should be sufficiently abundant and varied. It may be requisite that lactation be discontinued. It is sometimes advisable to caution against pregnancy. Digestion and assimilation are to be promoted by appropriate medical and hygienic treatment. The patient is to be withdrawn from the operation of toxical causes, lead, malaria, etc., and, as far as practicable, from all unsanitary influences which indirectly lead to the anæmic condition.

The quantity of wholesome food should equal, but not exceed, the digestive powers. Appetite and digestion should be promoted by quinia, salicin, and other tonic remedies. The articles of diet should be made attractive. Dyspeptic ailments are to be treated according to the indications to be hereafter considered (*vide* Sect. IV., Chap. V.). Out-of-door life, recreation, change of scene, daily sponging of the body, sea-bathing, and all hygienic measures which have a favorable influence on assimilation and conduce to invigoration, are useful.

The preparations of iron have a specially curative agency. Their *modus operandi*, with our present knowledge, cannot be satisfactorily explained. Doubtless, the fact that iron is a constituent of the red corpuscles of the blood affords a partial explanation. Nothing in practical medicine is better established than the value of iron as a remedy in simple or benign anæmia. Its

value is often attested by its efficacy even when the causes of the anæmia cannot be removed, and when other circumstances are unfavorable. If, in any case, it have no curative effect, there is reason to suspect that the anæmia is not simple or benign. On the other hand, the efficacy of the remedy is evidence that the anæmia is of that character.

Of the different preparations of iron, it is difficult to give decided preference to any one over the others. A physician is apt to have his favorite preparation, but that the choice is not based on the comparative merits of a considerable number, is shown by the fact that almost every preparation has its advocates. Iron reduced by hydrogen, the citrate, the hypophosphite, the tincture of the chloride, the tartrate, the carbonate, the compound mixture, are all eligible preparations. It is a good plan to change from one preparation to another, after a few weeks, giving thus several, or, it may be, many, of the different preparations in succession.

The chalybeate remedies should be given in moderate doses, after meals, that is, during the process of digestion, and, in order to secure their full efficacy, they should be continued uninterruptedly for a considerable and perhaps for a long period. It is well to state beforehand to a patient that all the good which they may accomplish is not to be expected within a brief period. This statement will be likely to secure patience and perseverance. Patients often think that they do not tolerate iron in any form. In general, they are self-deceived in this regard, as may be demonstrated by their ability to take it with no inconvenience if it be given without their knowledge.

Wine, especially Burgundy, is often useful. Here, as in other affections, alcoholics are of use only when they have a cordial effect, promoting assimilation and perhaps diminishing waste of tissues, without any excitant effects. Alcoholic excitation is always to be avoided, and the immediate effects, if in any way uncomfortable or disturbing, are contra-indicating. Malt liquors sometimes agree better than wine. Spirits, as a rule, are not appropriate. As to the kind of wine or malt liquor to be preferred, experience in each case is to be the guide. Cod-liver oil, if it do not impair the appetite or disorder digestion, contributes to the reproduction of red corpuscles. If not well borne, the extracts of malt may be substituted.

In cases of anæmia, assurances of the absence of any grave disease, and an encouraging prognosis, are often of much weight as a therapeutical factor. Despondency is an effect of the anæmic condition upon the mind, and the physician, in many cases, has it in his power, not only to remove gratuitous apprehensions, but to do not a little toward a cure by holding out proper expectations of recovery.

Chlorosis.

Although the chief element in chlorosis is undoubtedly anæmia, it presents certain peculiarities which render its separate consideration appropriate. The impoverishment of the blood in chlorosis has reference chiefly to the red corpuscles, and in a less degree to the albuminous constituents of the plasma. There is a reduction in the quantity of hæmoglobin in the red corpuscles, either with or without a diminution in their number. It is especially in chlorosis that a reduction in the percentage of hæmoglobin has been found without a corresponding decrease in the number of red corpuscles. Cases have been observed in which the number of red corpuscles was normal, while less than one-half of the proper amount of hæmoglobin was present. This condition of disproportionate diminution of hæmoglobin is called achroiocythæmia or oligochromæmia (see Part I. p. 62). Usually, however, the number of corpuscles is lessened, as well as the percentage of hæmoglobin.

According to Virchow, an almost constant lesion in chlorosis is arrest of development of the vascular system, as indicated by the small size and the thin coats of the aorta and other arteries. The intima of the arteries sometimes contains yellowish spots and streaks in consequence of fatty degeneration. Most observers do not consider these irregularities in the vascular system as a constant and essential change in chlorosis. Arrest in development of the female generative organs has been observed in cases of chlorosis, but, on the other hand, they often present no abnormalities. No especial importance, therefore, can be assigned to anatomical changes in these parts, as entering into the causation.

Aside from the foregoing differential points, the term chlorosis is applied to anæmia occurring in girls at or near the period of puberty, usually between the ages of fourteen and twenty-four, the causes often not being apparent. The term denotes a greenish coloration pertaining to the facies; but this is by no means a criterion. By some writers chlorosis is regarded as a neuropathic affection not always associated with anæmia; while, as it seems to me, anæmia is a constant element, there are doubtless causes which act upon the nervous system primarily and more directly than by inducing impoverishment of the blood. The development of the affection is evidently in some way connected with the evolution of the sexual system. How far the causation may involve, on the one hand, ungratified sexual desire, or, on the other hand, unnatural self-abuse, it is difficult to say. There is ground for the belief that each of these causative agencies is not infrequently operative. Disappointment in love, the loss of relations, and crosses of various kinds may be involved. These less apparent and other secret causes may act in conjunction with those already stated as giving rise to simple or benign anæmia (*vide* page 375). Blondes are said to be more liable to become chlorotic than brunettes. The affection, however, is not exclusively confined to girls. It is occasionally, owing probably to similar causative agencies, met with in boys.

The symptoms which have been enumerated as belonging to the clinical history of simple or benign anæmia are more or less marked in cases of chlorosis. Fantastic perversions of appetite are not uncommon in chlorotic girls, manifested by a craving for chalk, slate, charcoal, and other innutritive substances. These perversions are somewhat distinctive of chlorosis. The other points in the differentiation from simple or benign anæmia, are those which have been stated as characteristic of the chlorotic affection, namely, the sex, the age, the absence of an obvious, adequate causation, the probable connection with the sexual instinct, and, in some instances, the reduction in quantity of the hæmoglobin of the blood without diminution in the number of red corpuscles. As in simple or benign anæmia, the diagnosis requires an exclusion of the graver diseases of the hæmotopoietic system, and of other diseases of which anæmia is a symptom.

The treatment of chlorosis embraces measures, the same as in simple or benign anæmia, relating to diet, out-of-door life, etc., adapted to the circumstances proper to individual cases; and the preparations of iron, as a rule, are not less indicated and not less efficacious. The rules for their administration are the same. Mental hygiene is of special importance in proportion as causative agencies relate to the mind. Agreeable diversion and the moral effect of change of scene are often important measures of treatment. Occupations and sentiments which will displace sexual thoughts and desires, in some instances have a radical efficacy. This statement will include the instances in which self-abuse can be ascertained.

CHAPTER II.

LEUCOCYTHÆMIA.

THERE is a group of diseases characterized by a new growth of lymphatic tissue in various parts of the body. Lymphatic or adenoid tissue consists of reticulated connective tissue containing in its meshes lymphoid cells. This new lymphatic growth may be homologous or heterologous. It is homologous when in the form of hyperplasia of pre-existent lymphatic tissue, as of the spleen, lymphatic glands, and marrow of bone. It is heterologous when lymphatic tissue is produced in situations where it does not normally exist, as in the liver, kidney, skin, etc. It has been proposed to call these diseases with hyperplasia of the lymphatic structures, lymphatic diseases. Jaccoud describes them under the name lymphogenic diathesis. Common to all of these diseases is profound anæmia, generally progressive and fatal. The basis of classification usually adopted depends upon the number of white corpuscles present in the blood. When the pathological changes in the lymphatic tissues above mentioned are associated with marked increase in the number of white corpuscles, the name leucocythæmia is given to the disease. When the same pathological changes exist with anæmia, but without excess of white corpuscles, the disease is called pseudo-leucocythæmia. Pseudo-leucocythæmia includes splenic anæmia, lymphatic anæmia, and at least some cases of so-called progressive pernicious anæmia.

Leucocythæmia.

Leucocythæmia or leukæmia is a chronic disease characterized by a persistent and considerable increase in the number of white corpuscles in the blood. A temporary excess of white corpuscles, usually moderate in amount, is called leucocytosis (see Part I. p. 68). Alterations in the marrow of the bones, enlargement of the spleen, and hyperplasia of the lymphatic glands constitute, either singly or combined, the leading anatomical changes in leucocythæmia. Leucocythæmia is usually divided into three forms, called splenic, lymphatic, or medullary, according as the changes in the spleen, lymphatic glands, or the marrow of the bones seem to be primary and predominant. The medullary form is also called myelogenic leucocythæmia. These forms are usually combined with each other to a greater or less extent, and hence the terms lymphatico-splenic, medullo-splenic, etc. The subdivisions of leucocythæmia are not associated with essential differences in the clinical history, and are of importance chiefly as indicating that the anatomical changes may predominate in certain organs. There has been much difference of opinion as to the part primarily affected in leucocythæmia. The prevailing view has been that the primary alteration is in the spleen, or, more rarely, in the lymphatic glands. Changes in the marrow of the bones have been found, as a rule, since attention was called to them by Neumann. This pathologist maintains that they are constant, and form the primary lesion. It seems, however, probable that the changes in the spleen, the lymphatic glands, and the marrow of the bones are co-ordinate, and, in proportion to their degree, of equal importance; but the changes may be extensive in one

part and insignificant in the other parts. That they are ever exclusively confined to one of the parts named, has not been established.

The pathognomonic change in the blood may be detected during life in a drop drawn from the finger, or, after death, by examining the blood in the heart and vessels. The blood is paler than normal, and often unnaturally opaque. Its color has sometimes been compared to that of chocolate. The clots found in the heart and vessels are gray, yellow or reddish in color, and of a soft, viscous appearance, often resembling very thick pus. They are formed chiefly by fibrin inclosing large numbers of white globules. If blood drawn during life be defibrinated by whipping, there form, after a while, in the serum two layers of corpuscles, namely, a layer at the bottom of red, and, resting on this, a pale layer of white, corpuscles. The loss of red corpuscles is so great that, notwithstanding the increase of the white, there is a reduction in the total number of corpuscles in the blood. The proportion of white to red corpuscles in health varies within wide limits. The average in the adult appears to be about 1 white to 1000 red. In leucocythæmia the proportion of the former is frequently one to ten or eight of the red, and it may be as great as one white to three or two red. In many cases the proportion has been reported as equal, and in one case related by Sörensen there were three white to two red. In the vast majority of cases the proportion during the course of the disease exceeds one white to twenty red corpuscles. The increase of white corpuscles is said to be greater in splenic than in lymphatic leucocythæmia. Their size is usually normal, but it may be abnormally either increased or diminished. According to Virchow, the large variety of corpuscle is most frequent in splenic (splenæmia), and the small variety in lymphatic leucocythæmia (lymphæmia), but this relation is not sufficiently constant for diagnostic application. The corpuscles not infrequently contain molecules of fat. There are sometimes present aggregations of granules resembling the so-called elementary granules. The number of red corpuscles may be reduced to one or two millions per cubic millimetre, instead of the normal five millions. In Sörensen's case above mentioned, the number of red corpuscles was less than half a million in a cubic millimetre. The corpuscles may present the various changes described under anæmia in Part First (p. 62). They are usually of normal appearance, but they may be abnormally pale, or reduced in size (microcytes), increased in size (macrocytes), or irregular in shape (poikilocytes). The hæmatoblasts of Hayem may also be present in considerable number. The appearances, even as regards the number of white corpuscles, may vary considerably within a short time. Eisenlohr[1] describes a case in which the excess of white corpuscles nearly disappeared during a febrile attack, to return again after its subsidence. The specific gravity of the blood is lessened in consequence of a diminution of its solid constituents. The amount of fibrin is said to be increased.

Some degree of splenic enlargement is usually present in all forms of leucocythæmia. In *splenic* leucocythæmia, which is the most frequent variety, the enlargement is often extreme. According to Gowers,[2] the average weight of the spleen, in splenic leucocythæmia, is a little below 6 pounds, and its average length $11\frac{1}{4}$ inches. Leucocythæmic spleens weighing 16 and 18 pounds have been recorded. The increase in size is usually uniform in all directions. The notches upon the anterior border, the recognition of which may aid in the diagnosis, are often exaggerated. The capsule of the spleen frequently presents thickened white patches. There may be adhesions between the surface of the spleen and surrounding parts. The

[1] Eisenlohr, Virchow's Archiv, Bd. 73, p. 56.

[2] Gowers, article "Splenic Leucocythæmia," in Reynolds's System of Medicine.

consistence of the organ is usually increased, but it may be soft, especially in the early stages. The cut surface of the spleen may be uniformly brownish-red in color, or the Malpighian bodies may be prominent as whitish dots, or, when greatly enlarged, they may even appear as tumors in the substance of the spleen. The whitish trabeculæ may be much thickened, especially in the late stages. The spleen sometimes presents on section a mottled appearance from the presence of dark red or yellowish, wedge-shaped infarctions. These are ascribed to obstruction of certain of the splenic vessels by the accumulation of white blood-corpuscles. Softened spots due to hemorrhage and the disintegration of the splenic pulp, or to collections of pus, have been met with in leukæmic spleens. Microscopical examination shows the change to consist in a hyperplasia of the organ, that is, in an increase of the normal elements of the spleen. The hyperplasia affects chiefly the splenic pulp, but sometimes to a greater extent the Malpighian follicles. Large cells containing coarse granules either of pigment or of fat are common in leucocythæmic spleens.

In the splenic and medullary forms of leucocythæmia the *lymphatic glands* are often more or less enlarged, and in the lymphatic variety an excessive hyperplasia of the glands is an early symptom. The abdominal, inguinal, cervical, and axillary glands are those most frequently affected. The single glands may attain the size of a hen's egg, but they are usually smaller. Their consistence is soft, rarely hard, and their color gray or reddish-gray. The microscope shows an adenoid reticulum infiltrated with lymphoid cells as in the normal glands. Allied to the affection of the lymphatic glands, there is sometimes a similar hyperplasia of the follicles of the tongue and pharynx, of the tonsils, and especially of the solitary follicles and Peyer's patches in the intestine.

The change in the *marrow of the bones* is to be included among the hyperplasias of lymphatic structures. The change consists in the disappearance, to a greater or less extent, of the fatty medulla normally present in the long bones of adults, and its replacement by a tissue rich in lymphatic cells. The alteration has usually been found in the long bones, the ribs, the sternum and the vertebræ. The altered marrow has either a greenish-yellow, purulent aspect, or a dark-red appearance resembling that present in the bones of embryos and infants, and in profound anæmias. Neumann calls the greenish-yellow transformation *pyoid*, and the dark-red *lymphadenoid*. There is less difference in the microscopical structure than the gross appearances would suggest. In the pyoid alteration, which is the more common, the yellowish color becomes somewhat reddened by exposure to the air. The marrow is of a soft pulpy consistence like that of creamy pus, but there is usually no real breaking down into pus, as a net-like reticulum can be demonstrated between the cells. The appearances have been in certain cases almost identically those of acute osteo-myelitis, and even purulent foci have been exceptionally detected. In the lymph-adenoid change, the marrow is dark red in color, and of a gelatinous consistence firmer than that of the pyoid marrow. The dark-red and the yellowish colors may be found side by side. The reticulum between the cells is better developed in the dark-red, than in the pyoid, marrow. In both there is a rich capillary net-work. In both the cells resemble the normal medullary cells and those present in the blood. Sometimes large granular, at other times smaller and less granular, cells predominate. Nucleated red corpuscles are present, but not usually in large number. The hyperplasia, when excessive, is at the expense of the surrounding bone-substance, which thereby becomes more or less rarefied. The sternum, in rare instances, may become softened through its entire thickness, and swollen by hyperplasia of the marrow and absorption of bone. This softening may be detected dur-

ing life. These changes in the marrow have been studied most carefully by Neumann, who regards them as the most constant and important of the pathological changes in leucocythæmia. This pathologist[1] divides the twenty cases, which he has collected, of leucocythæmia with medullary changes, into three groups: *first*, those without any enlargement of the spleen or lymphatic glands (3 cases); *second*, those in which the changes in these organs were insignificant and out of proportion to the extensive blood-alteration (3 cases); and, *third*, cases with well-marked hyperplasia of the spleen and lymphatic glands (14 cases). Cases have been reported in which the changes in the marrow seemed insufficient to account for the alteration in the blood. The extreme views of Neumann have not met with general acceptance.[2]

Changes are also observed in leucocythæmia in non-lymphatic organs. These changes are either diffuse or circumscribed and nodular. The diffuse alteration consists in the distension of capillaries, and the infiltration of the tissues with white blood-corpuscles. The circumscribed changes consist in the nodular accumulation of leucocytes either with or without a new growth of adenoid reticulum between the cells. To these nodular accumulations, the names heteroplastic leucocythæmic growths, lymphomata, and lymphadenomata are applied.

The liver is enlarged in the majority of cases, especially of the splenic variety. A weight of six or seven pounds is not uncommon. Virchow describes leukæmic livers weighing from eight to fourteen pounds. The enlargement is due to a distension of the capillaries with leucocytes, and to the infiltration of the tissue between and within the lobules with these cells, probably in consequence of their escape from the vessels. Disseminated whitish nodules, usually minute, but sometimes of considerable size, consisting of lymphoid cells, are frequently found in the interlobular tissue. These nodules are called lymphadenomata when an adenoid reticulum can be demonstrated between the cells.

The kidneys are not infrequently enlarged. The changes are diffuse and circumscribed as in the liver. Parenchymatous alterations may, or may not, be present. Tizzoni has described infiltration and nodules of lymphoid cells in the testicles. Leucocythæmic growths may furthermore be scattered through different parts of the body, as the alimentary tract, the lungs, the serous membranes, the brain and the retina (Friedländer), the skin (Biesiadecki), etc.

Next to these accumulations of lymphoid cells, deserves mention the frequent occurrence of hemorrhages in leucocythæmia. Subserous ecchymoses, hemorrhages into serous cavities and from mucous membranes, retinal and cerebral hemorrhages may be mentioned as frequent and important. The gums and the mucous membrane of the mouth and pharynx may be swollen and ulcerated. The lymphoid growths in the intestine may ulcerate. Pronounced fatty degeneration, especially of the heart and kidneys, has been repeatedly observed.

Various abnormal substances have been found in leucocythæmic blood. These are a body analogous to glutin, hypoxanthin, leucin, tyrosin, and acetic and formic acids. These substances have not been uniformly discovered. Some are normally present in the spleen. There are frequently found after death, minute colorless, elongated, octohedral crystals, called Charcot's crystals. They have been detected in the blood, the spleen, the

[1] Neumann, Ueber myelogene Leukämie, Berlin klin. Wochenschrift, 1878, No. 6, 7, 9, 10.

[2] Fleischer and Penzoldt have reported a case of lymphatic leucocythæmia without change in the marrow of the bones. Deutsches Archiv f. klin. Med., Bd. 26, p. 368, 1880.

marrow of the bones, the liver, and even in other parts. They are thought to be of an albuminous composition. Although most abundant in leucocythæmia, they have been found in other conditions, and they may form after death in healthy marrow.

There have been several theories as to the relation in leucocythæmia between the morbid change in the blood and the hyperplasia of the lymphatic structures. Bennett, to whom we owe the first recognition, in 1845, of leucocythæmia as a distinct disease, maintained that the change in the blood was primary, and the same view has had its advocates in recent years. Most modern pathologists, however, have accepted Virchow's doctrine that the increase of white corpuscles in the blood is secondary to the pathological changes in the lymphatic organs, to which is assigned a blood-forming function. Some have emphasized chiefly the affection of the spleen, others that of the marrow of the bones. According to one theory, there is an insufficient transformation of white into red corpuscles in the blood-forming organs and in the blood; according to another, there is increased production of white corpuscles, an exaggeration of the cytogenic function. The most probable view seems to be that there is increased formation of white corpuscles in the spleen, the lymphatic glands, and in the marrow of the bones, sometimes chiefly in one, sometimes in all of these organs. From these hyperplastic organs the corpuscles are swept in large numbers into the blood and the lymphatic currents. Either the production of red corpuscles is diminished, or their destruction increased.

The development of leucocythæmia is usually slow and imperceptible. Before the character of the disease is determinable, general debility, indisposition to exertion, disorders of digestion, and other indefinite ailments have existed for one or two years, and sometimes for a much longer period. In exceptional cases, oftener in children than adults, it is developed within a few weeks. Early and prominent symptoms are those referable to impoverishment of the blood. Pallor of the face, prolabia and mucous membranes, and dark coloration of the eyeballs, are more or less marked, as in cases of benign anæmia and chlorosis, for which the disease in its early stages is liable to be mistaken.

Coincident with the anæmic symptoms is enlargement of the spleen. This enlargement, if not great, may not have attracted the attention of the patient. The enlargement, however, is often so great as to form a splenic tumor which occasions a projection obvious to the eye. The tumor may occupy a considerable part of the abdominal space. It has been mistaken for an ovarian tumor. It may cause dislocation of the heart, and, by pressure on the diaphragm, interference with respiration. Pain and tenderness referable to the enlarged spleen are frequent, but not constant, symptoms.

In the so-called lymphatico-splenic variety there is swelling of the glands of the neck, groin, and axilla, forming soft, movable tumors rarely of much size. The mesenteric glands are sometimes enlarged, so as to be felt through the abdominal walls. The bronchial glands may be enlarged, but rarely to an extent sufficient to occasion notable bronchial obstruction. The glandular swelling may occur either early or late in the progress of the disease. If the disease involve the marrow of bones (medullo-splenic and myelogenic leucocythæmia), there may be found over these, particularly the sternum, tenderness and sometimes swelling but, as a rule, local symptoms are wanting.[1]

[1] The changes in the marrow of bones, and, also, in the lymphatic glands, are considered by many as secondary to the blood-change, and due to the migration of the white corpuscles. *Vide* article in the Trans. Clin. Society of London, by W. Moxon, vol. ix. Also, article by Prof. Howard, in the Montreal General Hospital Reports, vol. i., 1880.

Dyspnœa is a symptom more or less prominent, attributable to the paucity of red corpuscles. It may be caused, in addition, by enlargement of the spleen and also of the liver, the latter occurring frequently. The dyspnœa is increased, and may be rendered extreme by hydrothorax in connection with general dropsy, and in some instances pleurisy with effusion.

General dropsy occurs sooner or later in a large proportion of cases. It may be independent of cardiac or renal disease, but the latter is a complication in some cases. Hydroperitoneum is sometimes produced by the pressure of enlarged glands on the vena portæ, and the accumulation of liquid may be so large as to call for paracentesis.

The action of the heart is increased in frequency, often considerably, and paroxysms of palpitation, during which the pulse is 150 or more per minute, are not uncommon. Hæmic murmurs are common as in benign anæmia and chlorosis. The temperature of the body is in most cases raised. Different cases differ in respect of the amount of pyrexia. It is generally moderate (from 100° to 102° Fahr.). Occasionally there is hyperpyrexia. Usually, there are febrile exacerbations in the evening. The temperature is found to fluctuate between wide limits at different times, in the same case, during the progress of the disease. The course of the disease is rapid in proportion to the degree of persistent pyrexia.

The liability to hemorrhage is such that a hemorrhagic diathesis may be said to constitute a prominent feature of the disease. Mosler emphasizes the importance of recognizing this diathesis as contra-indicating surgical operations in cases of leucocythæmia. He relates a case in which the patient nearly died from an insignificant operation, the bleeding having been stopped only by continuous digital compression.[1] Hemorrhages may occur early in the disease. The most frequent seat is the nose. Epistaxis may prove the immediate cause of death. Enterorrhagia, gastrorrhagia, and menorrhagia are not rare. Bronchorrhagia and hæmaturia have been observed. Cerebral hemorrhage is a cause of death in some cases. Cutaneous ecchymoses are among the events incident to the disease, and extravasations beneath the skin, in muscles, inclusive of the heart, and into joints. Eisenlohr has reported a case in which peripheral paralysis of several cranial nerves was caused by hemorrhage into their sheaths.[2] Friedländer[3] has reported a case in which the symptoms of cerebral tumor were caused by leucocythæmic growths in the brain.

Among events pertaining to the digestive system may be mentioned inflammation of the pharynx and mouth, accompanied sometimes with ulcerations and sometimes with bleeding from surfaces not ulcerated. Tumors of the character of lymphoma are sometimes developed in the throat. The appetite varies in different cases, and at different periods in the same case. It may not at first be diminished, and it may even be inordinate; but in the latter part of the disease there is generally anorexia. Vomiting is an infrequent symptom. Diarrhœa is a frequent symptom, and the dejections are sometimes dysenteric. Jaundice is an occasional event.

The urine has an excess of uric acid. Hypoxanthin, formic acid, and lactic acid have been found in small quantities, not, however, constantly. Albumen in any considerable quantity, and casts denote the existence of renal disease as a complication.

Salzer was the first to call attention to persistent priapism without seminal emissions or sexual desire, as an occasional symptom in leucocythæmia.[4]

[1] Ueber hämorrhägische Diathese bei Leukämae. Zeitschrift für klin. Medicin, Bd. i. p. 265. He observed a case in which priapism lasted seven weeks, and when this symptom disappeared, the power of erection was lost.

[2] Virchow's Archiv, Bd. 73.

[3] Virchow's Archiv, Bd. 77.

[4] Berl. klin. Wochenschr., 1879.

Others have observed this symptom. Dr. G. L. Peabody has recently reported a case.[1] Another case has been reported still more recently by Dr. G. F. Wetherell.[2]

The following morbid appearances in the retina have been observed by means of the ophthalmoscope: A pale appearance of the retinal vessels, hemorrhagic spots with white centres from an accumulation of lymphoid cells, whitish streaks, and cloudiness of vessels about the optic papilla. The name leucocythæmic retinitis has been applied to these changes. They may, or may not, give rise to notable disturbance of vision. The retinal hemorrhage may be sufficient to cause blindness. Headache, vertigo, feebleness of the mental faculties, delirium, and chronic derangement of mind occasionally enter into the clinical history. To these may be added impairment of hearing, furuncles, and pustular eruptions on the skin.

The limits of the duration of leucocythæmia are far apart. In very rare instances it runs a rapid course, ending within a few weeks. On the other hand, its duration may extend over many years. The average duration is about two years. It is not always easy to ascertain the duration, owing to difficulty of fixing the precise date of its commencement. The termination often depends on events which are incidental to the disease, or on complications, such as hemorrhage, apoplexy from extravasation, pleurisy, renal disease, diarrhœa, etc. If not dependent on any of these events, death is produced by slow asthenia.

The prognosis is as grave as possible after the disease has made a certain degree of progress. In some instances, early in the course, it has ceased to be progressive and recovery has taken place. If, with great blood-changes, the spleen becomes much enlarged, and more or less of the grave events belonging to the clinical history have taken place, there is little or no ground, with our present knowledge, for any expectation of recovery. The most to be hoped for is that the disease will progress slowly, and that events which involve immediate danger may not occur.

The clinical history of leucocythæmia from the beginning to the end of the career of the disease, contains diagnostic characters, but not sufficiently distinctive, in all cases, for the differentiation from pseudo-leucocythæmia and pernicious anæmia. In an early period of the disease, when a diagnosis is desirable, it is liable to be mistaken for other diseases in which anæmia coexists with splenic enlargement. A positive diagnosis, however, is always practicable by means of examinations of the blood. Delay or failure in the recognition of the disease is owing to neglect of the means by which the diagnosis is made.

The diagnostic criterion is a persistent and progressive increase of the white corpuscles of the blood beyond the limit of the variations embraced under the name leucocytosis. This name embraces a greater or less increase of the white corpuscles, occurring as a symptom in various diseases, the increase falling short of that which constitutes the criterion of leucocythæmia (*vide* Part I. page 68). The rule generally accepted, as regards the increase requisite for the diagnosis, is a proportion of one white corpuscle to twenty red corpuscles. As already stated, the proportion is often much greater than this, the number of white being sometimes equal to that of the red corpuscles. On the other hand, in the early part of the disease, the proportion may be

[1] N. Y. Med. Journ., May, 1880.

[2] N. Y. Med. Record, Aug. 14, 1880. Two other cases are reported in the N. Y. Med. Journal, Sept. 1880.

considerably less than one in twenty; and if, on repeated examinations, the proportion be found to progressively increase, there can hardly be doubt as regards the diagnosis.

The method of examination ordinarily employed is to obtain a drop of blood by pricking the finger of the patient, and, placing it in the field of the microscope, to estimate with the eye the relative proportion of the white and red corpuscles. A more accurate method is to add to a measured quantity of blood a definite quantity of a five or six per cent. solution of sulphate of soda, in order to dilute the blood, and to prevent the red corpuscles from forming rouleaux. The field of the microscope is divided into squares, by the aid of which the corpuscles can be easily counted. The squares are ruled either upon the eye-piece or upon the cell containing the diluted blood.[1] It is to be observed that the relative proportion of the white and red corpuscles does not show the degree of actual increase of the former, inasmuch as the red corpuscles are always considerably, and sometimes very greatly, reduced in number. Hence, the most exact method is to ascertain the number both of white and red corpuscles in a given quantity of blood by means of the hæmatometer or hæmacytometer.

Leucocythæmia occurs at all periods of life; it has been observed in infants soon after birth, and in extreme old age. In the great majority of cases, however, patients are between twenty and fifty years of age. It is less rare in men than in women. Social position has no marked influence on its causation. It occurs in women sufficiently often after parturition to show some causative connection. In a considerable proportion of cases, patients with this disease have either had malarial fever or been exposed to malaria. The disease is less rare in malarial districts than in those in which the periodical fevers do not occur. It is, therefore, reasonable to attribute to malaria a certain degree of causative agency. The white corpuscles have been found, in some cases, to contain black pigment-granules, such as are characteristic of malarial disease. Mosler applies to these cases the name *malano-leucæmia*.

The disease in a few instances has been preceded by local injury in the splenic region. There is little or no ground for attributing the disease to syphilis. In most cases the disease is developed in persons who, at the time of its development, were apparently in good health. These statements express all that is at present known of the etiology.

Diminution of the volume of the spleen has been thought to be an important object of treatment, under the supposition that the leucocythæmia will be diminished in proportion. With reference to this object, various measures have been employed, namely, quinia in full doses, hypodermic injections of ergotin, the iodide of potassium, the cold douche, ice applied over the spleen, and the application of electricity. Each of these measures has appeared, in some cases, to have produced, in a limited degree, the desired effect, but in other cases to be useless. It cannot be said that clinical experience has established the therapeutic value of any measure employed for the object just stated. Extirpation of the spleen has been resorted to in at least thirteen cases, in all with a fatal result, death resulting either from hemorrhage or peritonitis. The liability to fatal hemorrhage is enough to render the operation unwarrantable.[2] Were the operation warrantable, or were it practicable to reduce con-

[1] A convenient apparatus for counting the corpuscles is the hæmacytometer of Gowers. Still more exact is the apparatus of Zeiss.

[2] *Vide* Nedopil, Die Laparosplenotomie, Wiener Med. Wochenschrift, 1879, No. 9, 10, and 11.

siderably, by any measure of treatment, the size of the spleen, it is by no means certain that the leucocythæmia would be controlled; the supposed pathological connection between the latter and the splenic enlargement is theoretical. Moreover, the gravity of the disease does not depend on the excess of the white corpuscles in the blood. In pseudo-leucocythæmia and pernicious anæmia, kindred diseases in which there is not a considerable excess of white corpuscles, the gravity is not less than in leucocythæmia.

Neither arsenic, nor phosphorus, nor any remedy has as yet been found to have a curative influence over this disease. The treatment, therefore, resolves itself into meeting symptomatic indications, and adopting means, medicinal and hygienic, which may succeed in arresting the progress of the disease, improving the general condition of the patient and prolonging life. These objects of treatment will embrace the prolonged use of preparations of iron, the various tonics which are likely to improve appetite and promote digestion, hæmostatic remedies and appliances, an alimentation as abundant and nutritious as possible, cod-liver oil as a nutrient, favorable climatic influences, out-of-door life, mental diversion, and all available sanitary measures with reference to nutrition and general invigoration.

CHAPTER III.

PSEUDO-LEUCOCYTHÆMIA. HODGKIN'S DISEASE.

PSEUDO-LEUCOCYTHÆMIA designates an affection in which anatomical changes similar to those in leucocythæmia are present, without an increase of white corpuscles in the blood. In many cases the anatomical changes are apparently identical in both diseases. In such cases it seems unscientific to make one symptom, namely, the presence of an excess of white corpuscles, the basis of classification. In justification of this, however, it may be said that the difference in the state of the blood, not improbably, depends upon anatomical conditions which have not yet been recognized. Lymphatic, splenic, and, perhaps, medullary varieties may be distinguished in pseudo-leucocythæmia upon the same grounds as in leucocythæmia. In the majority of cases the lymphatic glands are primarily and most extensively involved. Hence, the lymphatic form is the one generally meant when the term pseudo-leucocythæmia is used without qualification. A medullary variety has not been recognized generally, but certain cases of progressive pernicious anæmia probably belong to this subdivision. To these, reference will be made in the next article. In splenic pseudo-leucocythæmia the spleen is the part mainly affected. This variety has been called also splenic anæmia and simple hypertrophy or tumor of the spleen. It is not to be confounded with the chronic enlargement of the spleen due to malarial infection. In splenic pseudo-leucocythæmia the lymphatic glands are usually, if not always, involved, but to a less extent than in the lymphatic variety of the disease. As the affection of the spleen and that of the lymphatic glands are usually combined, it is no more possible to draw a sharp line of distinction between the splenic and the lymphatic variety than between the same forms of leucocythæmia.

While the splenic variety of leucocythæmia is much more common than the lymphatic, the reverse is true in pseudo-leucocythæmia. The anatomical changes in the spleen are similar to those in leucocythæmia, and need not be repeated. A nodular enlargement of the Malpighian follicles is more frequent than in leucocythæmia.

The following names are in use to designate the lymphatic or most frequent variety of pseudo-leucocythæmia: Hodgkin's disease,[1] adenia (Trousseau), lymphatic anæmia (Wilks), malignant lympho-sarcoma (Langhans), malignant lymphoma (Billroth), lymphadenosis (Ranvier, Gowers). The name pseudo-leucocythæmia was introduced by Cohnheim. It is probable that a number of different pathological conditions have also been described by these names, especially by the term lympho-sarcoma. Scrofulous enlargements of the lymphatic glands, enlargements confined to a single group of glands, and the rare cases of primary sarcoma beginning in one group of glands and forming metastases in various parts of the body, but not by preference in other lymphatic glands, are to be excluded from the disease under consideration. In this affection, several groups of glands, sometimes nearly all in the body, are involved. In a large proportion of cases the spleen and the liver are enlarged. Secondary deposits may be present in most parts of the body.

The change in the lymphatic glands consists in an increase of the cells and of the reticulum. Virchow and later writers distinguish two forms of lympho-sarcoma, the soft and the hard. In the soft variety the glands are large, soft, almost fluctuating, of a gray or reddish-gray color, and often beset with ecchymoses. The enlargement is due to a new growth of lymphoid cells, between which is a delicate reticulum with wide meshes. In the hard form the consistence of the swollen gland is firm, the color grayish or yellowish-white, and, with the hyperplasia of the cells, there is a new growth and a thickening of the reticulum or stroma, denser and more marked than in the soft lympho-sarcoma. There are transitional forms between the hard and soft variety. In many cases the hard is a later stage of the soft enlargement. In the same case the characters are not always uniform; some glands may be hard and others soft. It is, therefore, not desirable to make a sharp distinction between hard and soft lympho-sarcoma, although there are undoubtedly cases in which the hyperplasia of the reticulum predominates from the onset, the glands in no stage of the affection having been soft. It is the soft variety which corresponds most closely in the anatomical appearances of the lymphatic glands with leucocythæmia. The name pseudo-leucocythæmia is sometimes limited to this variety; and it is true that in not a few cases the indurated form bears little resemblance to leucocythæmia. The enlarged glands may reach the size of a hen's egg. They may remain distinct or may become compacted together into a nodular mass, in which the individual glands can no longer be distinguished. In the latter case there has been either a periadenitis or an extension of the lymphatic growth into the capsule of the gland and surrounding connective tissue. The skin over the swollen glands is, as a rule, freely movable, rarely adherent. Upon section of the glands the normal distinction between cortex and medulla is usually obliterated. In the harder tumors often shining, more or less hyaline, masses of fibroid tissue may be detected. Fatty and caseous degeneration are very rare, a circumstance

[1] Hodgkin published his observations in 1832 (Medico-Chirurgical Trans., vol. xvii. p. 69), before leucocythæmia was known. He first called attention to coincident enlargement of the spleen and of the lymphatic glands as a distinct disease. His description included, undoubtedly, cases both of leucocythæmia and of pseudo-leucocythæmia. Some writers apply the name Hodgkin's disease to lymphatic leucocythæmia as well as to pseudo-leucocythæmia.

which distinguishes lympho-sarcomatous from scrofulous enlargements. The affection begins oftenest in the cervical glands. It has a tendency to involve especially the glands along the great vessels; hence, the retro-peritoneal glands are more frequently affected than the mesenteric. The starting point of the disease may be in the mediastinal glands.[1] The affection may remain for a considerable time stationary in one group of glands without impairment of the general health, and then rapidly increase and become generalized with the development of marked cachexia. The glands may attain to a large size without exerting compression upon surrounding bloodvessels, but in some cases there are severe symptoms resulting from pressure on the vessels, the air-passages, etc.

The spleen is enlarged, according to Gowers, in four-fifths of the cases. The increase in size may be enormous, but, as a rule, it is much less than in leucocythæmia. In the smaller number of cases the appearance is that of a diffuse hypertrophy of the splenic pulp; in the majority there are disseminated whitish growths in the form of nodules throughout the spleen. These are probably hypertrophied Malpighian follicles and growths in the peri-arterial sheaths. Infarctions may be observed as in leucocythæmic spleens. In the liver there may be lymphoid nodules or a diffuse infiltration of the interlobular tissue with lymphoid cells. In the latter case grayish streaks surround the acini. The hepatic capillaries may be distended with blood. As pointed out by Schulz, the secondary lymphoid formations in the different parts of the body involve especially the walls of the vessels. These secondary growths have been met with in nearly all parts of the body, as the kidneys, the serous membranes, the testicles, the lungs, the brain, the retina, the skin, etc. The thymus, the solitary follicles, and Peyer's patches may be diseased as in leucocythæmia. The marrow of the bones may present a reddish appearance as in pernicious anæmia, and may contain lymphomata. Further researches are required to determine the frequency and the character of the involvement of the marrow of the bones.

We are at present unable to explain the relations between pseudo-leucocythæmia and leucocythæmia. We do not know why apparently identical changes in the lymphatic structures should be attended in one case by increase of white corpuscles in the blood, and not in another case. The theory that in pseudo-leucocythæmia there is some obstacle to the passage of cells from the hyperplastic lymphatic glands into the blood or lymph-current, is plausible, but is not supported by any anatomical facts. Ackermann[2] has succeeded in injecting the afferent and the efferent lymphatic vessels of both the soft and the hard glands. He finds them pervious. According to Ackermann the corpuscles in the glands are larger in pseudo-leucocythæmia than in leucocythæmia. The fact that there may be the same changes in the spleen, lymphatic glands, and other parts in pseudo-leucocythæmia as in leucocythæmia, speaks against the view of those who hold that in leucocythæmia these changes are the result of a primary increase of white corpuscles in the blood. In some cases, especially of hard lympho-sarcoma, the origin of the growth appears to be local; in the majority of cases several groups of glands are affected simultaneously or in rapid succession. In such cases a primary dyscrasia is assumed to exist.

[1] R. Schulz (*Arch. d. Heilkunde*, Jahrg. 15, p. 223, 1874) has analyzed 38 cases with reference to the frequency with which different groups of glands are affected. The cervical glands were affected in 28 cases, the retro-peritoneal in 21, the inguinal in 20, the mediastinal in 18, the bronchial in 14, the mesenteric in 14, the lumbar in 12, the axillary in 9, the cubital in 4, the popliteal in 1.

[2] Ackermann, Ueber die malignen Lymphome, Diss. Bern. 1879.

The symptomatology of lymphatic pseudo-leucocythæmia embraces the events which belong to the clinical history of leucocythæmia, namely, general debility, feebleness of the circulation, hemorrhages, general dropsy, pleuritis, and other complications, together with the varied phenomena referable to persistent, progressive anæmia. A distinctive feature is the occurrence, uniformly earlier and more extensive, of enlargement of lymphatic glands, and often the development of lymphoid tumors where these glands are not normally discoverable. The cervical glands are affected in a great majority of cases, and in most of these cases primarily. The aggregated enlarged glands may attain to a large size, causing much deformity. Next in frequency are affected the axillary glands. The glands in the anterior and posterior mediastinum, the bronchial, the cardiac, the retro-peritoneal, the mesenteric, and the inguinal glands may be, severally or collectively, the seats of the local affection. Lymphatic growths may be found in the tonsils, the thorax, the soft palate, the posterior part of the tongue, the œsophagus, and beneath the skin. Perhaps the most remarkable case on record, as regards the extensive distribution of these growths or tumors, was reported by Dr. James H. Hutchinson.[1] In this case, exclusive of enlarged cervical glands, of a tumor of the size of a hazel-nut on the upper eyelid, and of a large tumor involving the sternum and the anterior mediastinum, two hundred and thirty-nine tumors, ranging in size from a small pea to half a walnut, were counted on the surface of the body. There were twenty tumors on the surface of the brain. A tumor surrounded the bodies of the sixth, seventh, and eighth dorsal vertebræ, and extended within the spinal cord, causing complete paraplegia. Three hundred small tumors within the lungs were counted. Small tumors were scattered over the peritoneal covering of the intestines. It is noteworthy that in this case the spleen and liver were healthy. An unusual feature was the existence of intracranial lymphatic growths.

The pressure of the tumors in different situations may give rise to important symptoms. Pressure upon the larynx or trachea may obstruct respiration, and death is sometimes due to suffocation. Paralysis of the laryngeal muscles may be caused by pressure upon the recurrent laryngeal nerve. Obstruction of the bronchi may be caused by enlarged bronchial glands. The heart is sometimes dislocated. The œsophagus, in rare instances, is obstructed. The cervical tumors may diminish the arterial supply to the brain by pressing on the carotids, or they may induce venous congestion by pressure upon the jugular veins or the vena cava. Deafness is not infrequently produced by growths within the pharynx. The pneumogastric nerve may be involved in a tumor, and the action of the heart thereby retarded. Pain in the upper or lower bowels may result from pressure upon the nerves in the axillary and inguinal regions. The femoral vein may be compressed and œdema of the lower limb follow. Jaundice is sometimes attributable to pressure upon the bile duct. Gastric symptoms and diarrhœa may be symptomatic of lymphoid growths in the stomach and intestines.

The duration of pseudo-leucocythæmia, like that of leucocythæmia, varies from a few weeks to many years. Of 42 cases analyzed by Dr. Hutchinson, in 29 death took place within two years, and in 34 within three years. The average duration is a little less than that of leucocythæmia.

As regards causation, as little is known of this disease as of leucocythæmia. In the larger number of cases, the age is between ten and thirty years; but the disease sometimes occurs in childhood and in extreme old age. A decided influence pertains to sex, a large majority of patients being males. An etiological agency referable to antecedent diseases, or to habits of life, or to

[1] *Vide* Trans. College of Physicians of Philadelphia, third series, vol. i., 1875.

any appreciable morbid influences, has not been established. The disease is often developed in persons who at the time of development apparently were perfectly well.

The diagnostic criteria of lymphatic pseudo-leucocythæmia are the symptoms common to this disease and to leucocythæmia, taken in connection with the affection of the lymphatic glands, and the fact that there is not an increase in the white corpuscles of the blood sufficient to constitute the leucocythæmic condition. The affected lymphatic glands do not undergo the processes of necrosis and suppuration which characterize scrofula; nor are there the gradual invasion of adjacent parts and the ulcerations which characterize the local history of carcinoma.

The prognosis is no better than in cases of leucocythæmia. The supposed instances of recovery in an early stage are open to the suspicion of an error of diagnosis. There are probably very few, if any, exceptions to the rule of a fatal termination when the disease is so far advanced that the diagnosis is positive. The progress of the disease may be either slow or rapid. It is rapid in cases with pyrexia, profuse hemorrhage, and considerable anasarca. The extent of the distribution, and the degree of the glandular growths, constitute a measure of the tendency to a rapid progress. The immediate cause of death may be an important complication, such as disease of the kidneys, purulent pleuritis, etc. The pressure of the tumors on important parts may lead to the fatal ending. Irrespective of these causes, the disease proves fatal by slow asthenia.

Measures of treatment have been directed especially to the affected glands. The external application of iodine, the employment of cold and heat, frictions, blisters, the injection into the tumors of iodine, nitrate of silver, carbolic acid, arsenic, and other topical remedies, and galvano-puncture, have been tried, with but little if any satisfactory result. Excision of the affected glands has been repeatedly resorted to, but the efficacy of this measure has not been established. The removal of the tumors, or their dispersion by any local treatment, would not strike at the root of the disease. An unknown essential pathological condition underlies the affection of the glands. This condition cannot be reached by any therapeutical appliances as yet ascertained. Excision, however, of enlarged glands may be advisable with a view to relieve parts, such as the larynx or trachea, sensory nerves, etc., from pressure. The internal use of arsenic, the doses increased to the utmost limit of toleration, and conjoined with the injection of Fowler's solution into the affected glands, has been advocated by Winiwarter as a useful method of treatment, but the utility which he attributed to it has not been confirmed.

Aside from any treatment instituted with the hope of effecting a cure, the objects and the measures are those stated in connection with leucocythæmia.

CHAPTER IV.

PERNICIOUS ANÆMIA.

THE name pernicious anæmia is given to a severe, often fatal, form of anæmia, for which, in many cases, we are unable to assign a sufficient cause either before or after death. The following are some of the synonyms for this disease: idiopathic anæmia (Addison), essential anæmia (Lebert),

progressive pernicious anæmia (Biermer), anæmatosis (Pepper), myelogenic pseudo-leucocythæmia (Pepper). It has also been described, in some of its special manifestations, under the names, puerperal chlorosis (Lebert), extreme anæmia of pregnant women (Gusserow), and anæmic form of fatty heart (Ponfick). We owe to Addison the first recognition of this disease. He described it clearly and concisely under the name idiopathic anæmia in his celebrated memoir on disease of the supra-renal capsules.[1] He also called attention to the coincidence of fatty degeneration of the heart with this form of anæmia. Cases were subsequently described by Wilks, Lebert, Barclay, and others. In the year 1871 a number of cases of this disease were fully and carefully analyzed by Gusserow and by Biermer, at that time professors in Zurich. Biermer,[2] since whose publication especial attention has been directed to this disease, proposed for it the name progressive pernicious anæmia, which it has since retained. As the disease is not necessarily progressive and fatal, it seems best to adopt the simpler designation pernicious anæmia, as proposed by Quincke. Pepper and Tyson,[3] in the year 1875, first observed the changes in the marrow of the bones which usually attend this affection.

Although pernicious anæmia has no symptoms which may not occur in other forms of anæmia, there are, nevertheless, certain symptoms which, especially in combination with each other, are more frequent in the pernicious than in the secondary or symptomatic anæmias. These symptoms, which, therefore, are in a degree characteristic, although not pathognomonic, of pernicious anæmia, are an excessive degree of the anæmia, the preponderance of the anæmia over all other symptoms, the progressive and malignant course often uncontrolled by therapeutical agents, the absence in many cases of emaciation, the appearance of fever without anatomical basis, the intensity of heart-murmurs without valvular lesions, retinal hemorrhages, and the frequent prominence of digestive disturbances. Upon post-mortem examination, fatty degeneration of the heart and certain changes in the marrow of the bones are observed with a greater degree of constancy and of intensity in pernicious than in symptomatic anæmia. The clinical history, taken in its entirety, is therefore sufficiently characteristic to justify us in assigning a separate place to this disease.

Great obscurity and differences of opinion exist in regard to the *etiology* of pernicious anæmia. It is agreed that this form of anæmia is to be separated from that which accompanies certain general diseases and structural changes in the body which are known to lead to profound and often fatal anæmia. Conditions thus accompanied by severe symptomatic anæmia are, malignant tumors, Bright's disease, phthisis, leucocythæmia, splenic and lymphatic pseudo-leucocythæmia, syphilis, severe malaria, and the presence of certain entozoa (anchylostomum duodenale). The anæmia symptomatic of some of these diseases in certain cases may present a group of symptoms similar to, and even identical with, those of pernicious anæmia. As a rule, these affections present certain symptoms or signs which lead to their diagnosis. But it sometimes happens, in cases of severe anæmia, that the exclusion of some of these conditions is not easy nor even possible during the life of the patient; and upon post-mortem examination they may escape detection, or their recognition may depend in an unusual degree upon the knowledge and skill of the pathologist. Hence it is that a certain degree of uncertainty surrounds the

[1] Addison, On the Constitutional and Local Effects of Disease of the Supra-renal Capsules. New Syd. Soc. ed. of his works, London, 1868, p. 212.

[2] Biermer, Correspondenzblatt für Schweizerische Aertze, Jahgr. 2, No. I., 1872.

[3] Pepper, Progressive Pernicious Anæmia, Amer. Journ. of the Med. Sciences, Oct. 1875.

diagnosis in many cases of pernicious anæmia. An example will make clear the difficulty here involved. It has repeatedly happened that profound anæmia has developed for which no explanation could be found until the autopsy revealed a cancer of the stomach which had presented no physical signs nor diagnostic symptoms during life. The anæmia in such cases is to be regarded as symptomatic and not as pernicious, no matter how closely the symptoms may have resembled those of pernicious anæmia.

While most authorities[1] are agreed in separating these symptomatic anæmias from pernicious anæmia, there is diversity of opinion as to the relations between simple and pernicious anæmia, and as to the adequacy of certain causes which precede the development of the latter disease. According to some writers, pernicious anæmia is not an independent disease, but it differs from simple anæmia only in the intensity of the anæmia. As expressed by Quincke, pernicious anæmia represents the highest potency of simple anæmia. This view is based chiefly upon the fact that the same causes which induce simple anæmia often precede the development of pernicious anæmia, and that the one form merges into the other. A number of cases of pernicious anæmia, especially of those reported by Gusserow and by Biermer, attended or followed pregnancy and the puerperal state, conditions in which simple anæmia is often present. Often-repeated pregnancies with short intervals between them, and prolonged lactation have been assigned as exciting causes. To this same group of causes belong exhausting discharges such as diarrhœa, repeated hemorrhages, insufficient food, mental anxiety, poverty, and antihygienic surroundings—in a word, conditions which lead to prolonged inanition. Pernicious anæmia has also been observed to follow typhoid fever. Endemic influences have also been thought to be of importance in the etiology of this disease. This opinion is based upon the fact that a remarkably large number of cases have been reported by physicians in Switzerland. This fact seems to be attributable, in part, to the bad quality of food among the poor in that country. Many cases have been described in other countries, and it is improbable that importance is to be attributed to endemic causes except as they may involve unfavorable conditions of living.

It is difficult to say how much weight is to be assigned to the various causes which have been named. A large number of individuals who are subjected to them, develop simple anæmia; only a very small minority develop pernicious anæmia. It is the opinion of Immermann that these causes are to be regarded only as accessory causes of pernicious anæmia; that, while they may explain a certain degree of anæmia, they are wholly inadequate to explain its progressive and pernicious character. This writer makes an essential element in his definition of pernicious anæmia, the absence of any known sufficient cause of the disease, and this is implied in the term idiopathic anæmia. In opposition to this view, Quincke holds that we must regard these conditions as, in fact, efficient causes of pernicious anæmia. These causes, he argues, like others with which we are acquainted, act upon different individuals with different degrees of intensity. Persons differ in their vulnerability or power of resistance to these causes. Pernicious anæmia, as he contends, bears to simple anæmia a relation comparable to that between pernicious and simple intermittent fever, between grave and simple icterus, between a pronounced diabetes mellitus and a simple glycosuria. Pernicious anæmia, according to this author, is not a separate disease, but is simply a convenient name for a number of pathological processes.

[1] Quincke in his most recent publication (Deutsches Archiv f. klin. Med., June, 1880) includes under pernicious anæmia even profound symptomatic anæmias, such as the anæmia secondary to cancer.

These among other considerations certainly render somewhat vague the boundaries of the signification attached to the term pernicious anæmia, and render it impossible to draw a sharp line of distinction between it and simple anæmia. But a separation upon the following basis seems justifiable: When the resulting anæmia, which may be extreme, is in proportion to the intensity of the cause, when its degree can evidently be explained by the action of the cause, and when, upon the removal of the cause or causes, it disappears under proper treatment, unless the strength has already been too greatly reduced, the anæmia is simple—not pernicious. When, however, the degree of the anæmia is greater than experience shows to be fairly attributable to the intensity of the cause, and when its progress, even after removal of the cause, remains unchecked notwithstanding appropriate means of relief, then, unless there are other opposing grounds, the diagnosis of pernicious anæmia may be made. If in the latter case the alleged cause or causes be regarded as alone sufficient to produce the pernicious anæmia, we must either assign to them an exceptional virulence out of proportion to their usual effects, or attribute to the patient an exceptionally weak resistant power.

Pernicious anæmia may develop without any of the causes mentioned, or similar causes. Several cases have been reported in which the disease appeared in persons of apparently unimpaired constitutions and in the best hygienic surroundings. It was especially with reference to these apparently spontaneous cases that Addison was led to assign an independent position to the disease under consideration. Pernicious anæmia seems to be somewhat more frequent among women than among men, but not with that disparity which the early statistics showed. It has been observed at all ages, but is less frequent at the extremes of life than between the ages of twenty and forty.

Inasmuch as some writers assign a much broader significance to pernicious anæmia than other writers, it is explicable that certain observers place under this heading some cases which others do not regard as pernicious. It is, moreover, probable that certain obscure forms of profound anæmia, which now receive a provisional shelter under this name, may be relegated by future investigations to other categories. In illustration of this may be cited the grave form of anæmia known as Egyptian chlorosis, which prevails in Egypt and some other tropical countries. This presents a clinical picture strikingly similar to that of pernicious anæmia, and was once regarded as an idiopathic anæmia. It has now been proven in many cases to depend upon the presence of a small intestinal parasite called anchylostoma duodenale, to which reference will be made in Section IV. In Italy the diagnosis of pernicious anæmia has been made during life, and this parasite detected after death.[1]

The most important of the anatomical changes in pernicious anæmia relate to the blood. It is probable that in many cases there is a diminution in the quantity of blood out of proportion to the reduction in the weight of the body. Such a true oligæmia was proven by Quincke to exist in two of his cases. The small amount of blood often found in the bloodvessels and heart, after death, renders probable a reduction in the total volume of the blood. A diminution in the mass of blood, however, is usually more a matter of inference than susceptible of actual proof. An essential change in this disease is the loss of red blood-corpuscles, or oligocythæmia. The number of red corpuscles in a cubic millimetre of blood can be estimated with accuracy by the hæmacytometer of Gowers or by the apparatus of Hayem and Nachet. It is thus found that in pernicious anæmia the number of red corpuscles may be reduced from one-third to one-tenth of the normal amount.[2] A drop of

[1] Morelli, Virchow u. Hirsch's Jahresbericht, 1878, Bd. II. p. 261.

[2] The normal number of red corpuscles in a cubic millimetre of blood is 5,000,000. Hayem (Gaz. Méd. de Paris, March 6, 1880) designates as *oglobulie intense* a globular

blood presents an abnormally pale appearance. Quinquaud found in a fatal case the percentage of hæmoglobin reduced to 2.6 per cent. (instead of the normal 12 to 14 per cent.).

The degree of oligocythæmia is greater than that usually met with in other forms of anæmia. Not only is the number of red corpuscles diminished, but the percentage of hæmoglobin in the individual corpuscles may also be lessened. In that case the corpuscles are abnormally pale. The red corpuscles often present abnormalities in their shape. This condition of the blood has been called poikilocytosis (Quincke). Among the more frequent diversities of form may be mentioned pear-shaped corpuscles, corpuscles with a long tail-like process, corpuscles in the shape of a ring, and cup-shaped corpuscles presenting a deep, clear depression in the centre. There are often greater differences in size than in the normal blood. Large corpuscles, 12 to 14 micromillimetres in diameter, may be frequently observed, as well as abnormally small corpuscles, less than 6 micromillimetres in diameter. According to Hayem, the small corpuscles, usually called microcytes, represent developing red corpuscles, and are most abundant when the condition of the patient is improving. These changes in the shape and in the size of the red corpuscles are not peculiar to pernicious anæmia, but may be found in any intense anæmia; nor are they necessarily present in pernicious anæmia. Hayem finds that peculiar small yellow crystals form in dried specimens of blood from cases of intense anæmia. Most observers have failed to find in the blood nucleated red corpuscles such as are often present in considerable number in the marrow of the bones in this disease. Ehrlich claims to find, by a peculiar method of preparation, nucleated red corpuscles in the blood in all forms of severe anæmia, whether traumatic or essential;[1] and Hayem reports white corpuscles as frequently containing hæmoglobin in anæmic blood. The white corpuscles seem to be sometimes diminished in number as well as the red. In many cases, however, no change is to be observed. A relative leucocytosis is then present. In a case of pernicious anæmia reported by Litten,[2] the number of white corpuscles suddenly increased four days before death, and an actual leucocythæmia developed. Small white corpuscles (5–6 micromillimetres) are more abundant than in health. Accumulations of granules resembling white corpuscles, and known as granular formations or disintegrating corpuscles (Zerfallskörperchen), may be met with, although less frequently than in leucocythæmia. The blood coagulates less perfectly than in health. Fränkel[3] found in two cases of pernicious anæmia the solid constituents of the blood reduced nearly one-half. Quincke estimated the specific gravity in one case at 1028, instead of the normal 1055.

Almost without exception, in the fatal cases of pernicious anæmia there is more or less fatty degeneration of the heart. The fatty degeneration may be slight, and appear only as a yellowish mottling of the inner surface of the myocardium, especially on the papillary muscles; or the degeneration may be extreme and extend through the whole thickness of the heart. In a case reported by Ehrlich,[4] there was diffuse myocarditis. The heart may be small,

richness between 2,000,000 and 800,000; and as *aglobulie extrême* a globular richness between 800,000 and 450,000. The oligocythæmia in pernicious anæmia falls within the boundaries called by Hayem intense and extreme. There must have been some error in Quincke's observation (Deutsches Arch. f. klin. Med., Aug. 1877), who reports a case which recovered and which presented a reduction in the number of red corpuscles to $\frac{1}{35}$ of the normal amount (143,000).

or normal in size, or there may be dilatation of some of its cavities, especially of the right ventricle. The valves are generally intact. The observations of Ponfick, and the experiments of Perl demonstrate that the fatty degeneration is to be regarded as secondary to the anæmia. Fatty degeneration of the hepatic cells, and more rarely of the renal epithelium, has been observed.

In the great majority of cases of pernicious anæmia, although not invariably, the yellow or fatty marrow which is normally present in the long bones of adults is changed into the red or lymphoid marrow, resembling that found in embryos and infants. They who first observed this change (Pepper and Tyson, and Cohnheim), considered it as characteristic of pernicious anæmia, and thought that they had discovered the anatomical basis of the disease. It was the discovery of this alteration that led to the view that pernicious anæmia is the myelogenic form of pseudo-leucocythæmia. Subsequent observations have not tended to confirm this view. It appears that the same change in the marrow of the bones accompanies most anæmic and cachectic conditions by whatever cause produced. Microscopic examination of the altered marrow shows that the fat-cells have in great part disappeared, and have been replaced by abundant large and small, coarsely and finely granular medullary cells, resembling those normally present in the marrow. In addition, as first pointed out by Cohnheim, there are often in considerable number nucleated red corpuscles, as to the signification of which there is much diversity of opinion. The early observers considered them as transitional forms between white and red corpuscles. They interpreted the whole change as an increase in the blood-forming function of the marrow. There is much which speaks for this view, but it is far from established. In a few cases there has been observed a change in the marrow resembling the pyoid alteration of leucocythæmia. The medulla then presents a greenish-yellow appearance, sometimes with apparently purulent foci. The condition resembles that in acute osteo-myelitis. In a few cases, lymphomatous growths, or multiple growths resembling round-celled sarcoma, have been found, especially in the marrow of the bones, in the periosteum, and in the kidney.[1] In one case Weigert observed moderate enlargement of the lymphatic glands, and a distension of the lymphatic vessels in various parts of the body, with lymph containing numerous red blood-corpuscles. The spleen may be unchanged or it may be moderately swollen. Small extravasations of blood are usually found in different parts of the body. The most frequent seats of ecchymoses

[1] Cases of Fede, Grawitz, Quincke, Krieg, and Litten. The changes which are found in the marrow of the bones in pernicious anæmia, are now usually regarded as secondary to the anæmia, and are interpreted as not in favor of the view that the disease is to be considered a myelogenic pseudo-leucocythæmia. While the alteration usually observed does not resemble the pyoid marrow most frequently found in leucocythæmia, it does resemble the lymphadenoid or less frequent variety. It may be urged with equal propriety that this red marrow is secondary to the anæmia in leucocythæmia as well as in pernicious anæmia. The transition from pernicious anæmia to leucocythæmia, observed by Litten, can hardly be regarded as accidental, but suggests some relation between the two processes. Schepelern has also reported cases apparently transitional between progressive pernicious anæmia and leucocythæmia and pseudo-leucocythæmia. The symptoms of the two diseases are so nearly alike that an examination of the blood is often required before the diagnosis can be made. The cases of pernicious anæmia which have been reported with pyoid marrow and with secondary growths of tissue like that composing the marrow, certainly bear a very close resemblance to the myelogenic form of leucocythæmia, except in the number of white corpuscles in the blood. As has already been said, it is probable that the term pernicious anæmia is applied to various pathological processes, and there is reason to believe that some of these may be classified as myelogenic pseudo-leucocythæmia. By so doing, however, we gain no clearer insight into the nature of the disease.

are the retina, the inner surface of the dura mater, and the serous membranes. The hemorrhages in the retina are usually small, not more than a quarter to a half the diameter of the optic papilla. They are most frequent near the papilla and along the vessels. They often present a whitish or grayish centre. Sometimes an œdematous condition of the retina is present, in which case, during life, its vessels and the choroid appear clouded. Small aneurisms of the retinal vessels have been observed. More or less general œdema with dropsical accumulations in the serous cavities is common.

The anatomical changes found after death from pernicious anæmia do not explain the pathogeny of the anæmia. Two suppositions are admissible; there is either an abnormal destruction of the red corpuscles (hæmophthisis), or there is an incomplete and retarded formation of red corpuscles (anæmatosis). It is not improbable that both of these conditions are operative. Quincke has found in several cases an abnormally high percentage of iron in some of the organs, particularly in the liver. He interprets this as an evidence of destruction of red corpuscles.

The symptomatic phenomena in cases of pernicious anæmia, in so far as they represent a profound and persistent anæmic condition, are essentially those belonging to the clinical history of the grave hæmotopoietic diseases already considered, namely, leucocythæmia and pseudo-leucocythæmia. Anorexia, nausea, and vomiting are symptoms more constant and prominent than in the diseases just named. Many years ago I ventured to predict that the disease would be found to involve degenerative changes in the gastro-intestinal tubules. Further observations directed to this vast and important glandular system are yet to be made. In respect of the symptomatology, it will suffice to state the points embraced in the diagnosis.

The liability to the error of mistaking for pernicious anæmia that which is symptomatic of some obscure, grave local affection, especially carcinoma, has been already mentioned. This error cannot always be avoided. Investigations, however, should always be directed to the discovery of some local affection adequate to explain the anæmia. A positive diagnosis requires the exclusion of any such affection. A diagnostic point bearing on this inquiry relates to the nutrition of the patient. Addison called attention to the fact that in the cases of idiopathic fatal anæmia which he described, emaciation was not marked, considerable embonpoint being often maintained. As a rule, it is otherwise when anæmia is symptomatic of a grave affection like carcinoma. In some cases of pernicious anæmia, however, there is extreme emaciation.

Leucocythæmia is excluded by the absence of the characteristic blood-change expressed by the name. The white blood-corpuscles are not in sufficient excess to denote that disease. Pseudo-leucocythæmia is excluded by the absence of the affection of the lymphatic glands which characterizes the disease generally understood by that name, more commonly known as Hodgkin's disease.

The question arises not infrequently in cases of simple anæmia and chlorosis, in which the anæmic condition is unusually intense and rebellious, whether the anæmia be not pernicious. As bearing on this question, the following points are to be considered: An adequate discoverable causation renders it probable that the anæmia is benign. Yet, an anæmia traceable to causes which seem to be adequate, may prove to be pernicious. Intractability of the disease, after the removal of supposed causes and the faithful employment of appropriate measures of treatment, is proof of a pernicious character. Certain events belonging to the clinical history of pernicious anæmia rarely occur in benign anæmia and chlorosis, however protracted.

These events are hemorrhages in different situations, general dropsy, and pyrexia. Pyrexial paroxysms, of greater or less intensity, of variable duration, and irregular in their occurrence, are frequent in pernicious anæmia, as they are also in leucocythæmia and pseudo-leucocythæmia. The loudness of the hæmic murmurs—cardiac, arterial, and venous—is somewhat diagnostic of pernicious anæmia. Notable feebleness of the heart's action, pointing to fatty degeneration, has diagnostic significance. Sex has some weight in the diagnosis, the disease affecting women oftener than men, and especially during pregnancy. Age is also to be taken into account; in the majority of cases pernicious anæmia affects persons in the middle period of life, whereas chlorosis, in a large proportion of cases, affects young subjects. It remains to be determined by clinical observations how much can be inferred from the abnormal appearances of the red corpuscles, as regards the diagnosis. Impaired vision dependent on retinal ecchymoses is to be included among the diagnostic points, as well as the existence of ecchymoses without an appreciable impairment of vision. The employment of the ophthalmoscope, thus, is of importance with reference to the diagnosis. According to Quincke, ecchymotic spots in the retina are so frequent in pernicious anæmia, and so rare in other affections involving anæmia, that they have a significance almost pathognomonic. That author has also called attention to the occurrence in some cases of a systolic pulsation of the superficial cervical veins, without venous turgescence. Functional insufficiency of the tricuspid valve is the probable explanation of this sign which occurs sometimes temporarily in other connections.

The prognosis is affected materially by the latitude of the signification of the term pernicious in this application of it. If a fatal termination be essential for the disease to be considered as pernicious, of course there is no possibility of recovery. This is an extreme view. Guided by the analogy already mentioned to the relationship between simple and pernicious intermittent fever, it suffices for the application of the term that the anæmia presents an *ensemble* of the characters which distinguish it in the cases which do prove fatal. Cases have been reported presenting the requirements for the diagnosis of pernicious anæmia, in which recovery has taken place. Taking the view just stated, Biermer and Quincke report 6 recoveries out of 54 cases.

The duration of fatal cases varies from a few weeks to several months. The average duration is less than that of leucocythæmia and pseudo-leucocythæmia. Sudden death sometimes occurs from syncope. Cerebral hemorrhage may be the immediate cause of death. If the disease be developed during pregnancy, abortion or miscarriage takes place, the patient speedily dying. If death be not caused by either cerebral hemorrhage or syncope, the mode of dying is by slow asthenia.

The objects and general principles of treatment are sufficiently obvious. The removal of all causes which may have produced the disease or which render it persisting and progressive, is an object of prime importance. The substitution for these causes of all agents and influences which affect unfavorably the functions concerned in assimilation and nutrition, is the next important object. These objects are widely comprehensive, but it is not necessary to go into details. The same principles are involved as in the treatment of anæmia in all the grave diseases affecting the hæmotopoietic system. As an extreme measure, the transfusion of blood has been resorted to, but, thus far, without results affording encouragement to expect from it more than a temporary advantage. Reasoning *à priori*, more than this cannot be hoped for from this measure, inasmuch as it cannot reach the essential morbid conditions on which the anæmia depends.

CHAPTER V.

ADDISON'S DISEASE.

IN the year 1855 Dr. Thomas Addison[1] described an affection characterized by disease of the supra-renal capsules, by a peculiar discoloration of the skin together with certain mucous membranes, and by the development of progressive and fatal asthenia. This disease, in honor of its discoverer, is called usually Addison's disease. It has also received the names bronzed-skin disease, melasma supra-renale, and supra-renal capsular disease. Since the masterly description given by Addison, little has been added to our knowledge of this disease which still remains one of the most obscure in the nosology. The most important addition since Addison's memoir is, that the change in the supra-renal capsules presents certain well-defined anatomical characters common to the great majority of cases. It was thought by Addison that any disease of the supra-renal capsules was capable of producing the characteristic group of symptoms; it is now known that, with few exceptions, the morbid process in the capsules is a definite one, to which the name fibro-caseous metamorphosis is applicable.

Almost without exception both supra-renal capsules are involved. The change may be further advanced in one than in the other. The capsules are usually found to be enlarged, of firm consistence, and with nodulated surfaces. The size may equal that of a small hen's egg, but it is usually less. Sometimes the size is normal or even less than normal. The latter condition generally corresponds to a late stage of the process. Upon section, usually no trace of the normal parenchyma or of the distinction between cortex and medulla can be detected. The place of the normal tissue is occupied by opaque, yellow, friable cheesy masses, imbedded in firm, grayish, semi-transparent fibrous tissue. The proportion between these two substances varies; sometimes one predominates and sometimes the other. On close inspection gradual transitions from the grayish fibrous to the yellow cheesy material can often be seen. The caseous substance may become dry and calcified, or it may soften and form collections of thick creamy fluid resembling abscesses. The whole interior of the organ may be converted into a hard cretaceous mass, or into a cavity containing creamy fluid. In this case the organ may be much diminished in size. In some cases small grayish granulations resembling miliary tubercles can be seen around the cheesy material and in the fibrous stroma. The microscopical examination of the gray fibrous material shows a fibrillated, sometimes a reticulated, stroma containing fusiform cells, lymphoid cells and not infrequently giant-cells. The caseous substance consists of a granular detritus of albuminous and some fatty particles with remnants of cells. Little nodules, composed of lymphoid cells and giant-cells, in other words of tuberculous tissue, have been occasionally observed. As to the nature of this change in the supra-renal capsules, writers are not agreed. Some consider it as a chronic inflammation resulting in the formation of con-

[1] Addison on the Constitutional and Local Effects of Diseases of the Supra-renal Capsules, London, 1855.

nective tissue and in caseation of the inflammatory products. (Wilks.) Others regard the alteration as scrofulous or tuberculous in character. It resembles in gross and in microscopical characters the appearances in scrofulous or tuberculous lymphatic glands, and in the tuberculous processes in the lungs. In not a few cases undoubted tuberculous changes have been found at the same time in the lungs and in other parts of the body, but there have been many cases in which the alteration was confined to the supra-renal capsules. In the latter cases, if the process be regarded as tuberculous, it would be necessary to assume the existence of a local tuberculosis of the supra-renal capsules, an assumption so little in harmony with the views generally held as to the tuberculous diathesis, that most pathologists are unwilling to commit themselves to it. A certain relation between the changes in the supra-renal capsules and tuberculous processes, however, may be admitted. In the present uncertainty it is best to employ the designation fibro-caseous metamorphosis, as being non-committal, and, at the same time, expressing the anatomical appearances.

The altered capsules are usually found imbedded in a mass of indurated fibrous tissue which binds them firmly to surrounding structures, such as the liver, pancreas, kidneys, stomach, vena cava, and diaphragm. This overgrowth of connective tissue generally invades the important sympathetic nerves in the neighborhood of the supra-renal capsules, namely, the solar and supra-renal plexuses and the semilunar ganglia. Changes have been found, although not constantly, in these nervous structures. These consist in hyperæmia, swelling in consequence of thickening of the nerve-sheaths, fatty degeneration and atrophy of the nerve-fibres and ganglion-cells, and increased pigmentation of the ganglion-cells.

The mesenteric glands, especially those in the neighborhood of the supra-renal capsules, are usually enlarged and sometimes cheesy. It is not unusual to find enlargement of the solitary and agminated follicles of the intestine. In some cases the spleen has been found enlarged and softened. Tuberculous deposits in various parts of the body, are changes which some regard only as complications, and others as properly belonging to the disease. Indurated and caseous nodules in the apices of the lungs seem to be the rule; less frequent is general pulmonary tuberculosis. Caseous nodules have been found in the testicles, brain (solitary tubercles), and lymphatic glands. The carious condition of the vertebræ, which has been found several times as a complication, with and without lumbar abscessess, perhaps belongs to the category of tuberculous changes.

The discoloration of the skin and of certain mucous membranes, is due to the deposit of brown, or yellowish-brown pigment-granules in the lowest layers of the epithelium. In the skin it is found chiefly in the epithelial cells composing the two or three lowest layers of the rete Malpighi, and is most abundant in the layer next to the corium. Similar pigment granules have been found, exceptionally, in the connective tissue beneath the epithelium and about the bloodvessels; but this pigment, according to Perls, differs from that in the epithelium by containing iron. The deposition of pigment is essentially in the same anatomical elements as in the negro.

In some, but not the majority of cases, fatty degeneration of the heart has been noted, likewise parenchymatous degeneration of the heart, liver, and kidneys. Careful examinations of the blood are lacking. A deficiency of fibrin, a watery and pale state of the blood, small red corpuscles, and changes in form of red corpuscles are among the morbid changes which have been recorded. Nearly all writers regard anæmia as an important element in the disease. Wilks, however, contends that the essential condition is asthenia from weakened nerve-power, and not anæmia. Estimations of the number

of red corpuscles and of the percentage of hæmoglobin, by the modern instruments of precision, are needed. In one case, redness of the marrow of the bones has been recorded, but little attention has hitherto been paid to this point.

Before completing the description of the anatomical characters of Addison's disease, it is necessary to add that changes in the supra-renal capsules, other than the fibro-caseous metamorphosis, have been reported as associated with bronzing of the skin and the other symptoms of Addison's disease. Most of these changes have been due to primary or secondary cancer of the capsules. Primary cancer of the supra-renal capsules is very rare, and some of the cases so reported seem to have been in reality fibro-caseous metamorphosis. Secondary cancer is more frequent. In a large number of cases of carcinoma of the supra-renal capsules, no pigmentation of the skin was observed. Greenhow, who has analyzed those cases in which discoloration of the skin was present, comes to the conclusion that the pigmentation did not present the characters typical of Addison's disease. Very positive statements, however, have been made as to the identity of the pigmentation with that in Addison's disease. It must be considered unsettled how far other processes in the capsules than the fibro-caseous change are capable of producing the train of symptoms characteristic of Addison's disease. There are observations which strongly support the view that a variety of morbid processes in the supra-renal capsules may produce the symptoms of Addison's disease. On the other hand, apparently typical cases of Addison's disease, so far as the pigmentation and other symptoms are concerned, have been reported without any disease of the supra-renal capsules. In a large number of the cases reported as bronzed-skin disease without change in the supra-renal capsules, the pigmentation did not present the typical characters, or it was due to some of the numerous physiological or pathological causes of discoloration of the skin which have nothing in common with Addison's disease. There remains, however, a very small number of cases in which the pigmentation and the constitutional symptoms were the same as those in Addison's disease, but in which the supra-renal capsules were found to be normal.

There has been no explanation at all satisfactory of the relation between the three conditions which characterize Addison's disease, namely, the change in the supra-renal capsules, the pigmentation of the skin, and the constitutional affection. It is not within the scope of this work to enter into a discussion of the numerous theories which have been proposed. A brief mention of the leading views will suffice to bring out the points at issue. According to one theory, disease of the supra-renal capsules is primary and the cause of the symptoms. In opposition to this theory it is argued that the symptoms cannot be referred to an abolition of the functions of the supra-renal capsules, whatever those functions may be; for the capsules have been extirpated in animals, and have been destroyed in man by cancer and other processes, without bronzing of the skin or other symptoms of Addison's disease. Nothnagel has succeeded in producing in animals caseous inflammation of the supra-renal capsules without the sequence of Addison's disease. Physiological experiments have shown that these organs are not necessary to life. The theory that the symptoms of Addison's disease are due to irritation of supposed secreting-cells in the glands, by which their function is increased and deleterious substances are introduced into the blood, was advanced by Klebs, but is not based on established physiological facts, and has not met with favor. Appreciating the difficulty of referring the symptoms to interference with the function of the supra-renal capsules, many, even of those who regard the disease of the supra-renal capsules as primary, attribute the symptoms to in-

volvement of the adjacent sympathetic nerves and ganglia. This theory is advocated by Virchow, Schmidt, Greenhow, Jaccoud, Resel and many others. The objections raised against this theory are, that the alterations in these nervous structures are not constantly present, that similar changes are found in a variety of processes without any of the symptoms of Addison's disease, and that the affection of the sympathetic does not make any clearer the explanation of the characteristic symptoms. Rossbach maintains that Addison's disease is a general neurosis due to functional disturbance of the entire nervous system. Another theory is that disease of the supra-renal capsules and the characteristic symptoms are independent of any causative relation to each other, and are all the result of some common antecedent condition which Heschl, Buhl, and others seek in the blood. Buhl suggests the entrance of some morbific agent from without into the blood; in other words, he regards Addison's disease as infectious in its origin. Heschl emphasizes especially the tuberculous diathesis. Pepper ranks Addison's disease with pernicious anæmia, leucocythæmia, and pseudo-leucocythæmia among the anæmatoses, that is, diseases in which the primary change is a profound disturbance of the blood-forming functions. The theory that Addison's disease is primarily a general or constitutional disease seems as plausible as any other. In this connection it is proper again to call attention to the resemblance of the fibro-caseous changes in the supra-renal capsules to tuberculous processes, and to the frequent coincidence of Addison's disease with tuberculous changes in various organs of the body; but the observations are at present too contradictory and incomplete to base upon these analogies any theory.

The following is a description of the appearances of the skin and of the symptomatology, by Dr. Edward Headlam Greenhow, who has devoted special study to this disease, and has analyzed a larger number of cases than has been collected by any other writer :[1]—

"The peculiar change of color consists in a gradual darkening of the skin of various parts of the body, or even of the whole body. The aspect of this discoloration gives to the patient the appearance of belonging to one of the dark races of mankind. Most frequently it has a dusky, smoky, or yellowish-brown hue, but sometimes it is of an olive or green-brown color, and, when deepest, approaches in parts to the tint of negro skin. The discoloration is never uniform over all parts of the body, but commences earlier and becomes deeper on some or all of the exposed parts—the face, neck, dorsum of hands and fingers; and on those parts which are naturally the seat of more pigment than the general surface—the axillæ, abdomen, groins, genital regions, nipples, and especially the areolæ. The deep discoloration of these last may, in my opinion, be regarded as one of the most decisive external signs of Addison's disease, and the appearance of small, well-defined black specks, like black moles or freckles, on already discolored portions of skin, is, in my experience, another no less certain. Although sometimes universal, the discoloration is more frequently only distinctly obvious on certain parts of the body. Even in the latter cases, however, it probably affects in some degree the whole cutaneous surface, for on microscopical examination of parts of the skin which by contrast with the dark spots appeared normal, I have found deposited also in them, though in comparatively small quantity, the pigment which imparts the abnormal color to the skin. The transitions from the darker to the paler shades of the discoloration of different parts of the body are never abrupt; the darkest parts are never sharply-defined patches, but

[1] *Vide* Croonian Lectures on Addison's Disease. London Lancet, 1875. Also, monograph published in 1866.

merge insensibly into the lighter, or apparently normal, portions of the surface. There is, however, one marked exception to this rule. When the skin has suffered any superficial abrasion or injury, or when the patient has been blistered at some recent period, the injured parts not only become much darker than the surrounding portions of the surface, but they present defined margins, coinciding with the extent of the cutaneous injury. The cicatrices of deeper injuries, on the contrary, usually remain pale, and are surrounded by a distinct border of more or less dark pigment, contrasting strongly with the ivory-like hue of the cicatricial tissue. It does not, however, require actual abrasion of the skin to excite a greater deposit of pigment in certain parts; slight local irritation of the surface appears, in not a few cases, to have produced the same effect. I have myself seen dark streaks on the skin corresponding with the lines of pressure exerted on particular parts by petticoat strings and garters, and the same circumstance has been noted by others. In a case recorded by Mr. Nicholson, in 1872, it is stated that the patient, a baker's lad, presented on his shoulders dark stripes corresponding to the bands by which the basket he carried was slung at his back.

"The discoloration in Addison's disease is not entirely restricted to the skin, being also frequently found upon the mucous membrane of the lips, cheeks, and gums, and also upon the tongue. On the lips it takes the form of an irregular bluish-black streak, running lengthwise, near the junction of the mucous membrane and outer skin. It is seen on the gums and buccal mucous membrane in the form of irregular stains and patches, mostly of a brownish color, with ill-defined margins. In two of my own cases the stains on the buccal mucous membrane have certainly corresponded with seats of irritation, produced by the pressure of ragged, protruding teeth; but in other cases I have been unable to verify any such cause. The discoloration of the tongue appears usually in sharply defined stains of a purplish-black or sometimes inky hue; and, in my cases, these stains have always been situated near the margins of the organ. On the other hand, the conjunctivæ have always remained normal; and the contrast between their pearly whiteness and the dusky hue of the discolored skin is very striking, and involuntarily recalls the similar contrast in the mulatto or negro countenance.

"We see, therefore, that the discoloration of the skin in Addison's disease usually begins, and eventually becomes deepest, on those parts which are naturally the most liable to become pigmented, either by exposure to sun and air, or by the excitement of certain physiological processes; and to these must be added such parts as may accidentally be subjected to the excitement of local irritation. In other words, this peculiar change of color is, like many other pathological processes, merely an exaggerated, and therefore a morbid, development of a natural physiological process."

Greenhow describes the constitutional symptoms as follows: "Gradual progressive asthenia, often originating without any apparent cause, and seldom dating from any definite period; great languor and indisposition for exertion, with, in advanced cases, breathlessness and palpitation, frequent sighing or yawning, and generally faintness on making any muscular effort, sometimes even on being raised up in bed. There are almost invariably great weakness of the heart's action and remarkable feebleness of pulse; loss of appetite; irritability of stomach, with nausea; and, toward the close of the illness, at least occasional, and often persistent, vomiting. The mind is generally clear to the last, but so great is the prostration in the latest stages of the disease that the patient often lies in a drowsy, apparently semi-comatose state, from which, however, he can be roused by questions, and to these he generally gives pertinent, though slow and reluctant, answers. There are in many cases pains in the loins, hypochondria or epigastrium; and, more rarely, dimness of

sight, vertigo, and, near death, a tendency to incoherence or delirium. Death takes place from asthenia, and, often, rather suddenly." . . . "There is, in uncomplicated cases, comparatively little or no emaciation. The skin is soft and cool. The tongue is usually clean and moist until the last day of life."

The occasional occurrence of convulsions is stated by Greenhow, and, also, by Jaccoud. The convulsions are oftener partial than general. Pye Smith and others have observed cases which terminated with severe cerebral symptoms, namely, delirium, coma, etc.

All writers dwell upon the frequency and prominence of gastric symptoms, namely, anorexia, nausea with more or less vomiting, eructations, cardialgia, etc.[1] In the early stage of the disease, the bowels are generally constipated, but at a later period diarrhœa is not infrequent.

As regards the urine, Thudicum found diminution of uric acid and of coloring matter. Rosenstern ascertained that the excretion of urea is diminished, and that there is an increase of indican.

The course of this disease is progressive, but its progress is not always continuous. Greenhow's observations show, in certain cases, paroxysms of progress, exacerbations, and remissions. During a remission, the discoloration of the skin is lessened, and there may be more or less general improvement. Exceptionally, the disease runs a rapid course. In these cases, bronzing of the skin usually precedes for some time the constitutional symptoms. In the vast majority of cases the progress is slow, the duration, however, being indefinite, extending sometimes over several months and sometimes over many years, the average duration being a year, or, according to Wilks, a year and a half.

The diagnosis is to be based on the characteristic bronzing of the skin together with the associated symptoms. A discoloration of the skin, bearing more or less resemblance to that of Addison's disease, may be referable to pityriasis, chloasma, protracted jaundice, the internal use of the nitrate of silver, the permanent staining which follows some syphilitic eruptions, and that caused by exposure, dirt, and the irritation of vermin, the latter described by Voght and by Greenhow under the name "vagabonds' disease." The associated symptoms representing the constitutional affection corroborate the diagnosis as based on the appearances of the skin. It is to be borne in mind that the bronzing of the skin may precede, as well as follow, the constitutional symptoms. Some delay, under these circumstances, may be requisite for a positive diagnosis. On the other hand, there is no doubt as to the occasional occurrence of cases of Addison's disease, as proved by the constitutional symptoms and by the characteristic changes in the supra-renal capsules, without any pigmentation of the skin. In these cases, generally either the duration of the disease has been brief, or it has been associated with grave complications. Brown patches in the mouth have been observed without bronzing of the skin. It is not very comprehensible that, associated with pyrexia, the disease should be mistaken for typhoid fever. The author of the article in *Ziemssen's Cyclopædia*, however, states that this mistake was made in a case under his observation. Litten, and more recently Krocker, describe pigmentation of the skin as a sequence of typhoid fever.

[1] Merkel, author of the article on this disease in *Ziemssen's Cyclopædia*, in a footnote mentions, "as a curiosity," that in the *Phil. Med. and Surg. Reporter*, June, 1871, an attempt is made to "refer the entire complex set of symptoms to degeneration of the glands of the stomach." If the attempt to connect the disease with glandular organs so vast and important as those which secrete the gastric juice be worthy of being mentioned only as a curiosity, how absurd would it have seemed to the author of that article to refer the disease to organs comparatively so insignificant as the supra-renal capsules, had he written his article prior to Addison's researches!

Addison's disease resembles the other grave diseases of the hæmatopoietic system in the obscurity of its causation. It occurs after adult age, in early or middle life, but very rarely in childhood and in advanced age. In a large majority of cases, patients are of the male sex, and a majority of these belong to the so-called working class. The character of the anatomical changes, and the not infrequent association with phthisis, justify the conclusion that a tuberculous diathesis may favor the development of the disease.

Writers agree that the prognosis in the present state of knowledge is fatal. But the duration of the disease sometimes extends over many years. It may remain non-progressive for an indefinite period, and, in some cases, notable improvement takes place. These are important facts to be considered with reference to the prognosis, and as affording encouragement in the treatment. In the absence of any remedies known to have a special curative efficacy, symptomatic indications are to be fulfilled, and treatment, medicinal and hygienic, pursued with reference to the same objects as in treating the other diseases of the hæmatopoietic system. In a case which came under my observation, the treatment by general faradization and galvanization of the sympathetic nerve, in the hands of Dr. A. D. Rockwell, was accompanied by marked improvement as regards the muscular strength and endurance; the sexual desire and capability, which had been lost, returned, and the bronzing became perceptibly less. This improvement continued for two years, when the patient suddenly, without any apparent cause, failed, and died within twenty-four hours.[1]

[1] *Vide* Med. and Surg. Electricity, by Drs. Beard and Rockwell, 2d ed., p. 675. For exhaustive articles in relation to this disease, the reader is referred, in addition to the works by Greenhow, to which reference has been already made, to Jaccoud, article Bronzée maladie, in Nouveau Dict. de Méd. et de Chirurg. Pratique, tome xi., 1866; and to Traité Pathologie Interne, tome ii., cinquième edition, 1877; to Overbeck, Die Addison'sche Krankheit., Erlangen, 1869; and to article by Pepper, in Am. Journ. of Med. Sciences, April, 1877.

SECTION FOURTH.

DISEASES AFFECTING THE DIGESTIVE OR CHYLOPOIETIC SYSTEM.

CHAPTER I.

INFLAMMATORY DISEASES OF THE LARGE INTESTINE.

Introductory Remarks. Anatomical Characters of Acute Dysentery. Sporadic Dysentery—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Epidemic Dysentery. Chronic Dysentery. Inflammation and Perforation of the Cæcum. Fecal Abscess. Inflammation and Perforation of the Vermiform Appendix. Colitis. Proctitis.

THE important organs composing the digestive system are, the mouth with the parotid, submaxillary, and sublingual glands, the pharynx and œsophagus, the stomach and duodenum, the small and the large intestine with the mesenteric glands, and the solid abdominal viscera, namely, the liver, pancreas, and spleen. Affections of the two outlets of the alimentary canal, namely, the mouth, pharynx, and œsophagus, with the appended glands, and the rectum and anus, properly belong to the department of surgery, being either open to view or accessible by manual exploration, and often requiring surgical operations. These affections, for the most part, will not be considered in this work. This section will, therefore, be devoted mainly to the diseases affecting the hollow viscera and the solid organs within the abdomen. The affections of the digestive system, as of other anatomical systems, consist of, *first*, inflammation; *second*, structural lesions; and, *third*, functional disorders. The inflammatory affections of the hollow viscera will be first considered. Inflammation affecting these viscera may be seated in the mucous membrane lining the alimentary canal, or in the investing serous membrane, the peritoneum. Inflammation seated in the mucous membrane may be limited to a section of the alimentary canal, namely, the portion lining either the stomach and duodenum, the small intestine, exclusive of the duodenum, or more or less of the large intestine. This is also true of functional disorders. I shall proceed to consider the inflammatory affections of the large intestine, taking up first the disease known as dysentery.

Anatomical Characters of Acute Dysentery.

The term dysentery has long been in use to designate an inflammatory disease of the large intestine characterized by mucous and bloody dejections and by tenesmus. As a name for the disease it is not very distinctive, its etymology simply expressing intestinal difficulty; but it is not easy to substitute a term conformable to the nomenclature of inflammatory affections, as there is no anatomical name for the large intestine as a whole. The term dysentery has the recommendation of not expressing any thing erroneous or doubtful in

regard to the pathological character of the disease. Acute and chronic dysentery claim separate consideration. Acute dysentery occurs as a sporadic and as an epidemic disease. This is a distinction of much clinical importance. After having considered the anatomical characters of sporadic and epidemic dysentery, these two forms of the disease will be treated of separately as regards clinical history, pathological character, etc.

Anatomical Characters.—After death from acute dysentery the mucous membrane of the large intestine is in a condition either of simple sero-purulent or of diphtheritic inflammation. Anatomically, therefore, the disease is distinguished as simple inflammatory, or as it is also called, in imitation of German nomenclature, catarrhal dysentery, and as diphtheritic dysentery. Most of the cases of sporadic dysentery are of the simple inflammatory variety, which is the milder of the two varieties. The largest number of cases of diphtheritic dysentery belong to the epidemic form of the disease. The anatomical, however, cannot be used interchangeably with the clinical, terms. Diphtheritic dysentery may occur sporadically, and epidemic dysentery usually includes a large number of cases of the simple inflammatory variety. There are, moreover, all grades of transition between the mildest cases of simple inflammatory dysentery and the most malignant of diphtheritic dysentery. It is not always possible during life to distinguish between simple and diphtheritic inflammation of the large intestine. For these and other reasons, it is most convenient to treat of the clinical history of acute dysentery under the headings, sporadic and epidemic dysentery, but to describe the anatomical appearances first of simple and then of diphtheritic inflammation of the large intestine.

Dysentery in the *acute simple* (catarrhal) variety is a simple inflammation of the inner coats of the large intestine. The inflammatory process is usually more intense in certain situations than in others. The parts most involved are the cæcum, the hepatic, and the splenic flexures of the colon, the sigmoid flexure and the rectum. These are the parts where the contents of the large intestine remain longest in contact with the mucous membrane. The inflammation often, although not invariably, increases in degree toward the lower end of the large intestine. The lower part of the ileum is also frequently involved in the inflammatory process.

The mucous membrane is reddened, softened, and swollen. The redness is usually in patches, and is most intense in the situations named. The color varies from light pink to dark, livid red. The redness is due chiefly to hyperæmia, as is evident from the arborescent appearance, especially marked when the intestine is examined by transmitted light. In addition to congestion, however, there are usually extravasations of blood in the mucous and submucous tissues, in the form either of punctate or of diffuse ecchymoses. It may happen that a congested appearance is not evident after death, as may be the case in inflammation of other mucous membranes. The surface of the mucous membrane is covered with a layer of tenacious mucus, either colorless or of a yellowish or brownish-red hue from admixture of bile and blood. Sometimes the admixture of pus is sufficient to give an opaque, yellowish color to the mucus. The mucus contains microscopically pus-cells, red blood-corpuscles, and desquamated epithelial cells. It is not certain that the epithelial cells have desquamated during life. The mucous membrane is sometimes so softened that it can readily be scraped off with the back of the scalpel. It is probable that this softening is, at least in part, a post-mortem change, as a similar condition is occasionally observed in cases where there has been no affection of the intestine during life. Both the mucous membrane and the submucous tissue are swollen, the latter often in a greater degree. This swelling is due to congestion together with the exudation of serum and of pus-cells. The solitary follicles are usually swollen, and appear

as grayish-white projections, about the size of a pin's head, surrounded by a zone of congestion. They may become as large as a small pea. Sometimes the inflammation seems to be chiefly in the follicles. The disease is then sometimes called *follicular dysentery*. If there have been repeated attacks of acute dysentery, or if the acute passes into a chronic stage, the mucous membrane becomes more or less pigmented. Points of dark pigment appear in the centre of the solitary and of the agminated follicles. In Peyer's patches this pigmentation gives rise to the so-called shaven-beard appearance. The pigment is mainly in the form of brown granules in the lymphoid cells. Diffuse patches and streaks of slate-colored or brownish pigmentation may appear outside of the follicles in the mucous membrane, especially in the large intestine. Small follicular ulcers, due to softening and breaking down of the follicles, are often observed in acute dysentery, especially in the follicular variety. The peritoneum over the parts most inflamed may be normal, or it may be coated with a layer of fibrin.

The microscopical examination shows the small veins and capillaries of the mucous membrane and of the submucous tissue, particularly of its upper layers, distended with blood. This change is, of course, best developed where the congestion is most evident to the naked eye. In some places there may be only hyperæmia, but, as a rule, there is distinct evidence of inflammation. This is afforded by the presence of pus-cells. The number of pus-cells varies in different cases, and may be considered, together with the ecchymoses, as an index of the intensity of the inflammation. The pus-cells are especially abundant near the muscularis mucosæ (Brücke's muscle) just below the glands of Lieberkühn, where there is normally a rich network of bloodvessels. The pus-cells are frequently observed in swarms around the small veins. There are also pus-cells in the mucous membrane between the glands of Lieberkühn; but as the connective tissue in this situation is of the variety called adenoid, which is normally densely infiltrated with lymphoid cells, it is difficult to determine here the presence of a moderate number of pus-cells, as these anatomically resemble the lymphoid cells. If the pus-cells accumulate in large number, they press apart and distort the glands of Lieberkühn. The enlargement of the solitary follicles is due to an increase in the number of lymphoid elements. These infiltrate the surrounding submucous tissue. In conformity with the views concerning inflammation advocated in Part I., page 36 *et seq*, the pus-cells may be regarded as emigrated white blood-corpuscles, although the possibility of their origin by proliferation of the normal cells, namely, the connective-tissue cells, the lymphoid cells, and the epithelial cells, cannot be denied. In addition to the emigration of white corpuscles, more or less red corpuscles escape by diapedesis. (Page 27.) The larger hemorrhages are the result of rupture of the vessel-walls (rhexis). The spaces between the fibres of the submucous tissue are distended by the presence of serum (œdema). As already said, the accumulation of lymphoid cells may be sufficient to compress the tubules of Lieberkühn. In this way the tubules may be obstructed in certain parts. They may undergo cystic dilatation below the seat of obstruction. Most of the epithelial cells lining the tubules are distended with mucus, and appear as so-called goblet or caliciform cells, forms which are normally very numerous in the large intestine. The fate of the columnar epithelium covering the inner surface of the mucous membrane is uncertain. As under normal circumstances this epithelium soon desquamates after death, its absence from its normal place in inflammation cannot be considered evidence of its separation during life. It is not probable that extensive desquamation of the epithelium occurs during life.

The description which has been given of the histological changes in acute simple inflammation of the intestine in dysentery, is applicable to the same variety of inflammation in other conditions, as in acute enteritis. It is espe-

cially the involvement of the lower part of the large intestine in the inflammatory process which characterizes acute dysentery. As is evident from the description, there are no changes in acute simple dysentery which may not undergo resolution, with the exception of the follicular ulcerations, which are by no means always present, and which may readily cicatrize. More or less pigmentation of the mucous membrane usually remains after an attack of dysentery.

Some writers describe a more severe form of purulent inflammation than that to which the name simple inflammatory dysentery has been given. In this, excessive suppuration occurs and ulcers are formed by destruction of the superficial layers of the mucous membrane. Follicular ulcers are present at the same time.

Dysentery with *diphtheritic or pseudo-membranous exudation* is a much graver disease than the simple inflammatory variety. It is called diphtheritic, not on account of any connection with diphtheria of the pharynx, but in consequence of the resemblance between its lesions and those of diphtheritic inflammation of the throat. It is also called fibrinous (croupous) dysentery, and corresponds in its more severe manifestations to the putrid and gangrenous dysentery of the old writers. Diphtheritic inflammation of the large intestine is characterized by the presence of an exudation containing fibrin, blood, and pus-cells upon the surface and in the substance of the mucous membrane, combined with sloughing and consequent loss of substance of the mucous membrane. A large number of cases of epidemic dysentery are of this type, but it may also occur sporadically.

According to Virchow, diphtheritic dysentery is always preceded by simple inflammation of the large intestine. Others believe that the inflammation may be diphtheritic from the onset. However this may be, diphtheritic inflammation is very frequently combined with simple inflammation. The morbid changes are usually, as in simple inflammation, most marked in the cæcum, the flexures, and the rectum, and affect by preference the projecting folds of the mucous membrane. The inflammation is often most intense in the sigmoid flexure and the rectum, and may be confined to these parts. Sometimes the rectum escapes. In other cases the inflammation is uninterrupted from the beginning to the end of the large intestine. In the lower part of the ileum, simple inflammation is frequently present, rarely diphtheritic inflammation. In the early stages of the diphtheritic process, the inner surface of the large intestine presents here and there patches of grayish-red, yellow, or variously discolored material, of varying thickness and extent, usually soft, but sometimes firm. This pseudo-membranous deposit consists of an exudation of fibrin, pus, and blood involving the upper layers of the mucous membrane. It extends in depth and destroys the vitality of the invaded tissue. The mucous membrane and often the subjacent tissues slough. In this way the so-called diphtheritic ulcers are produced, which may extend only in part through the mucous membrane, or they may expose the submucous tissue and even the muscular coat of the intestine. By further extension of the sloughing process, the wall of the intestine may be perforated and a fatal peritonitis induced. This occurrence is infrequent. The diphtheritic ulcers are irregular in shape, their walls bevelled or abrupt, in some cases overhanging. Sometimes little openings appear in the bed of the ulcer, which lead into dilated tubules of Lieberkühn. The ulcers may be so extensive that the undestroyed mucous membrane appears as scattered islands rising from the surrounding depressions. The mucous membrane may slough away in little shreds or in larger coherent masses, sometimes several inches in extent. In advanced cases the inner surface of the intestine, with the ulcerations, the pseudo-membranous deposits, the ridges of mucous membrane, the partially detached sloughs, all of various colors and consistence,

presents a peculiarly variegated appearance. Enlargement of the follicles and follicular ulcerations may likewise be present. The submucous tissue, where preserved, is usually much swollen and infiltrated with blood and pus. Submucous abscesses may form and undermine the mucous membrane. The peritoneal covering of the inflamed portion of intestine is congested and frequently coated with fibrin. Thus circumscribed and sometimes general peritonitis may occur, agglutinating the coils of intestine.

The microscopical examination shows sometimes distinctly fibrillated fibrin, inclosing red blood-corpuscles, pus, and epithelial cells, as a firm layer upon the surface of the mucous membrane, extending into the glands of Lieberkühn and infiltrating the substance of the mucous membrane. Frequently, however, the pultaceous deposits on the inner surface of the intestine present little evidence of structure, but consist of a mass of granular material, low vegetable organisms, and decomposed blood. In the sloughs of mucous membrane, careful inspection may reveal traces of the glands of Lieberkühn. These glands, when preserved, often present constrictions and cystic dilatations. These cysts may invade the solitary follicles. In the submucous layer a network of fibrin appears in the dilated interstices of the connective tissue, and especially in the lymphatic vessels. Hemorrhages and pus-cells are abundant. Colonies of micrococci are frequently observed in the coats of the intestine and in the pseudo-membranous deposits. It is difficult to assign to these and other forms of bacteria observed here, any pathological significance, as they are normally present in large number in the feces, and as decomposition rapidly attacks the sloughy masses in dysentery. Large granular endothelioid cells are observed in the submucous tissue, and are thought to be altered connective-tissue cells.[1]

When the sloughing process involves the mucous membrane of most of the large intestine, death is almost inevitable. Less extensive diphtheritic ulcerations may cicatrize. Granulation-tissue develops from the surface of the ulcer. (For the repair of ulcers, see Part I., page 40.) The cicatrix is composed of dense fibrous tissue covered with epithelium, but without glandular elements. The cicatrix is usually puckered, and causes some contraction of the surrounding tissue. Sometimes, but not frequently, stricture of the intestine, followed by grave and even fatal symptoms, is produced by the contraction of these cicatrices. The healing of these ulcers is slow and is attended by the symptoms of chronic dysentery.

Of changes in other organs of the body occasionally observed in diphtheritic dysentery, abscess of the liver deserves especial mention. This is a frequent complication in tropical climates. It is not frequent in this climate, but seems to be oftener observed here than in Great Britain and on the continent of Europe. The abscesses are usually multiple. They are explained by the transportation of infectious emboli, derived from thrombi in the mesenteric veins proceeding from the diseased intestine. The mesenteric glands are usually swollen, and may suppurate. Pulmonary complications, as pneumonitis and œdema, are frequent. Parenchymatous degeneration of the kidney and occasionally acute diffuse nephritis occur.[2]

The foregoing account of the anatomical characters is, of course, descriptive of appearances observed in fatal cases of sporadic and epidemic dysen-

Weigert and Eppinger speak of the occurrence of coagulation-necrosis as an essential element in the pathology of diphtheritic dysentery.

[2] An exhaustive consideration of the pathology and of other subjects pertaining to the natural history of diarrhœa and dysentery is given by Woodward, in the second medical volume of the Medical and Surgical History of the War of the Rebellion, Washington, 1879.

tery. It is to be added that, in either form, the disease is not infrequently so mild as to involve no danger, and hence in mild cases the opportunity of inspecting the parts after death is not offered. There are but few diseases in the nosology which offer a wider contrast than the mildest cases of sporadic and the gravest cases of epidemic dysentery. Without considering subacute dysentery as distinct, on the one hand, from the acute, and, on the other hand, from the chronic, form of the disease, cognizance will be taken of the fact of its occurrence in a mild form in treating of the clinical history, etc.

Sporadic Dysentery.

Clinical History.—Dysentery is generally preceded by simple diarrhœa, that is, more or less frequent and loose dejections of a feculent character. Of thirty-three recorded cases which I have analyzed with reference to this point, these dejections preceded the characteristic dysenteric evacuations in thirty. The latter appeared after the former had existed for a period varying from twenty-four hours to seven days.[1] With this prodromic diarrhœa there are colic pains, the appetite is impaired, and there is a general feeling of malaise. A pronounced chill rarely occurs, and even chilly sensations are not common.

The various ingredients which may enter into the composition of dysenteric stools are, feculent matter, mucus, blood, pus, serum, pseudo-membranes, necrotic tissue, bacteria and other low organisms, and undigested aliment. According to the preponderance of one or more of these substances, the stools are described as mucous, muco-purulent, muco-sanguineous, sero-sanguineous, sanguineo-purulent, gangrenous, bloody, purulent. It is the presence only of pseudo-membranes and of necrotic portions of the intestinal coats, which is characteristic of the diphtheritic form of inflammation. The other ingredients are common to both varieties of inflammation. The development of the disease is denoted by characteristic evacuations consisting of mucus, with which more or less blood is usually commingled. The quantity passed at each act of defecation is generally small, but the act is frequently repeated, slight evacuations often taking place every hour or two, and sometimes after intervals of a few moments only. The mucus is discharged in the form of clumps of a yellowish or reddish glairy material, sometimes without feces and sometimes around balls of feces. The quantity of mucus expelled, in some cases, is abundant, and forms a jelly-like mass not unlike a collection of the rusty sputa of pneumonitis. Microscopical examination of the mucous discharges shows cells resembling the white blood-corpuscles, called often in this situation mucous corpuscles, but in no way differing from pus-cells, red blood-corpuscles, bacteria, and sometimes cylindrical or flattened epithelial cells. The mucus itself is characterized by its viscid nature, and by its precipitation with acetic acid in the form of threads and flakes of mucin insoluble in an excess of the acid. When the mucous or pus-corpuscles are present in large number, the substance acquires an opaque whitish or yellow appearance, and is called muco-pus. The blood may give a diffuse or a streaky red color to the discharges. After the characteristic dysenteric stools appear, feculent matters are usually entirely absent. These may, however, appear at intervals, especially in the form of hard balls of feces, called scybala. When improvement begins, feculent matters appear in the stools. In mild cases the discharges may remain mucous throughout the whole course of the disease. In severe cases of sporadic, and frequently in epidemic, dysentery, the discharge of a sero-sanguinolent liquid occurs. The serous fluid is very rich in

[1] Clinical Report on Dysentery, based on an analysis of forty-nine cases, by the author. 1853.

albumen, of which large quantities may be precipitated, after filtration, by nitric acid. The amount of albumen is much greater than can be accounted for by the admixture of blood. It is the result of transudation of the blood-plasma. The characteristic stools of diphtheritic inflammation of the large intestine consist of a sero-sanguineous fluid containing small morsels of pseudo-membranous and necrotic tissue. These morsels have been compared to raw minced meat, and the yellowish-red fluid containing them was called by the older writers lotura carnium. The microscopical examination of these shreds and particles frequently shows only a mass of decomposing granular matter and bacteria mingled with blood-corpuscles and perhaps indistinctly fibrillated fibrin. In other specimens the fibrin may be more distinct. The examination of a sufficient number of specimens will usually bring to view some in which fragments of the tubules of Lieberkühn can be recognized, and thus the origin of these particles from necrosed intestinal mucous membrane demonstrated. These stools emit a peculiarly offensive, cadaveric odor. Less frequent than the presence of these small shreds is the discharge of large fragments of necrosed mucous membrane. These may be several inches in length. The stools containing them are dark in color, have a putrid odor, and are called gangrenous. The tubular pseudo-membranous casts, which have been described by some writers, are composed of inspissated mucus. They are very rarely observed in dysentery, but are present in a rare form of enteritis called membranous enteritis, muco-colitis, or tubular diarrhœa. Bacteria are present in dysenteric stools in enormous number. Fungus-spores and infusoria are occasionally observed. The stools may consist almost wholly of blood or they may be chiefly purulent. Little transparent clumps resembling granules of boiled sago or frogs' spawn have been seen in dysenteric stools. According to many writers they consist of masses of mucus moulded into a round form in follicular ulcers. According to Virchow they are colored blue with iodine, and are, in reality, undigested granules of starch. Woodward also considers them to be of a starchy nature. Dysenteric stools are usually alkaline in reaction and are said to contain carbonate of ammonia.

The inflammation of the rectum occasions a sensation as if this portion of the bowel were filled, and leads to the frequent desire to defecate, with as much straining as the soreness of the parts will allow. This desire to strain ineffectually is called *tenesmus*. Sometimes the straining efforts produce prolapsus of the intestine. The evacuations are frequently preceded by griping or colic pains which are called *tormina*. The tormina and tenesmus are not proportionate to the gravity of the disease; they are sometimes wanting in fatal cases, and are prominent symptoms in some mild cases. They are, however, the chief sources of suffering. Tenderness on pressure is in some cases more or less marked over the descending colon, and sometimes over the whole tract of the large intestine. It is rarely great, and not infrequently wanting. Meteorism or tympanitic distension is rarely present; the abdomen is usually depressed. Strangury and retention of urine are occasional symptoms, and, in the female, leucorrhœa may be produced. Redness and excoriation around the anus are apt to be produced by the irritation of the dejections. Perineal abscess is an occasional result of an extension of the inflammation. Intussusception, with the symptoms of ileus, sometimes occurs in children.

The pulse, in the majority of cases, is but little, and sometimes not at all, accelerated. The body heat is but moderately or slightly increased. Exceptionally, high febrile movement exists. The thermometer may show an increase of temperature to 103° or 104°. Great frequency of the pulse always denotes gravity and danger, but the converse does not hold good; in some fatal cases

the pulse is never much accelerated. The tongue may be frosted, or more or less coated, or it may present a natural appearance. During the course of the disease, the appetite is more or less diminished, or is lost. Thirst is usually present, and is sometimes urgent. Vomiting occasionally occurs, and may be prominent as a symptom, the matter vomited being of a greenish color. The intellect is unaffected as a rule, delirium occurring with great infrequency in cases which end in recovery, but occasionally, in cases which prove fatal, toward the close of life. The loss of strength varies greatly in different cases according to the intensity and extent of the local affection, depending, also, on the condition of the patient when attacked.

The duration of the disease, from the date of the attack to convalescence, varies from four to twenty-one days. These figures represent the minimum and maximum duration in thirty recorded cases.

Pathological Character.—Our knowledge of the pathology of sporadic dysentery embraces only the intestinal affection, the local and general phenomena which make up the clinical history being symptomatic of this affection. It is, however, probable that the inflammation, even in sporadic cases, is generally a local expression of an internal morbid condition of which we have at present no definite knowledge. This view is consistent with what will be presented under the head of causation.

Writers have described different varieties of the disease, distinguished as typhoid, bilious, intermittent and remittent, febrile and non-febrile, etc. These terms denote either variations in the phenomena of the disease or the co-existence of other diseases. Dysentery may occur as a complication of continued and of periodical fever. So rheumatism and dysentery are occasionally associated. These combinations are important in their practical relations, but it does not follow that the disease, under these circumstances, is specifically different from its ordinary form. Variations as regards febrile movement, supposed disorder of the liver, etc., do not affect the special character of the disease. Paralysis affecting certain muscles, especially the muscles of the lower limbs (paraplegia), has been observed, in some cases, to either accompany or follow dysentery; and different theories have been proposed to explain a supposed pathological connection between the paralytic and the dysenteric affection. The truth is, the affections are so rarely connected that their association is probably a mere coincidence.

Causation.—No age is exempt from liability to this disease, but, in the majority of cases, the patients are adults and under thirty-five. A larger number of males than females are attacked, but the preponderance is not sufficient to show that a marked predisposition relates to sex. The causation has a very obvious relation to climate. The disease is vastly more frequent, in the sporadic as well as epidemic form, in tropical than in cold and temperate climates. The causation has also a striking relation to season. Of forty-four cases which I recorded, all save one case occurred in July, August, September, and October. The constitution and previous health were good in one-half of the cases which I have analyzed, and in the remaining half there was no uniformity in character as regards the antecedent affections or disordered health.

Writers have been accustomed to state that the disease may be produced by various obvious causes, such as atmospherical changes, excess in eating and drinking, indulgence in acid, unripe fruits, crude vegetables, etc. But in the majority of cases its origin cannot be traced to these causes, nor to any obvious cause. This renders it probable that a special cause is often involved in sporadic, as well as in epidemic, dysentery. The limitation of the occur-

rence of the disease to the summer and autumnal season, and its more frequent occurrence in tropical climates, point to this conclusion, and to the agency of a high temperature in the evolution of the special cause. Persons who are in good health and vigorous are as likely to be affected as those who are feeble. Various circumstances standing in a causative relation to the disease in an epidemic form, may also be more or less frequently involved in its production when it is sporadic. These causative circumstances will be noticed in treating of epidemic dysentery.

Diagnosis.—The diagnosis of dysentery involves no difficulty. The characteristic evacuations are pathognomonic. It is to be discriminated from cases of bloody evacuations and irritation of the rectum incidental to hæmorrhoids, of intestinal hemorrhage or melæna, and of the discharge of pus from an abscess opening into the intestine. The points of contrast with dysentery which these cases offer are sufficiently apparent.

Prognosis.—Sporadic dysentery, in temperate climates, tends to recovery. It is a distressing disease, but attended with little danger to life. A fatal result is due either to an unusual intensity and extent of the local affection, or to an inability of the system to resist the disease from feebleness of constitution, or to some co-existing affection. The prognosis in tropical climates is less favorable. The recovery from the disease in temperate climates is almost always complete; that is, it rarely eventuates in chronic dysentery. Nor does it predispose to any other disease. In tropical climates, abscess of the liver is not an infrequent sequel. This very rarely follows in temperate climates. So far as my experience goes, immediate relapses are not apt to take place, and the occurrence of the disease diminishes the liability to its occurrence at a subsequent period. With reference to the latter point, my analysis of cases, although the number was not large, developed an interesting result. Of the cases recorded during fourteen years, in not a single instance was the disease known to recur. And in sixteen of these cases the patients were under observation after recovery during periods varying from one year to thirteen years. This result was the more striking from the fact that the patients for several years were within the sphere of an epidemic influence which, in some instances, affected other members of the same families.

Treatment.—Sporadic dysentery is a self-limited disease, and in the great majority of cases would end in recovery without medicinal treatment. In order to study its natural history, I allowed the disease in ten cases to pass through its course without any therapeutical interference. These were sporadic cases of average severity. They ended in recovery after an average duration of from eight to nine days. An analysis of forty-nine cases previously recorded, in which different methods of treatment were employed, gave about the same duration in the cases ending in recovery.[1] These observations are sufficient to establish the self-limitation of sporadic dysentery, and its intrinsic tendency to recovery; facts which, so far as I know, had not been before demonstrated by withholding all medication in a series of cases. But there is reason to believe that the disease is sometimes arrested, that its duration may be frequently abridged, and that the distressing symptoms may be greatly relieved, by judicious therapeutical measures.

It is desirable that, as early as possible, the fecal contents of the large

[1] *Vide* "A Contribution toward the Natural History of Acute Dysentery," in the Am. Journ. of Med. Sciences, July, 1875, and a clinical report based on analyses of 49 cases in the Buffalo Med. Journ., July, Aug., Sept., and Oct. 1853.

intestine should be effectually removed, in order to prevent their continued passage over the inflamed surface, and to secure, so far as may be, that important end in the treatment of all inflammations, namely, rest of the inflamed part. It would seem that nature endeavors to relieve the bowels of their contents by the diarrhœa which precedes the dysenteric evacuations. The first point in entering on the treatment is to ascertain if the bowels have been spontaneously relieved. With reference to this point, the size and character of the stools are to be ascertained, and the abdomen examined by palpation. In general, it is advisable to render the effort of nature more complete by giving an effective purgative. Castor oil has been in much repute as an appropriate remedy, but, aside from the objection on the score of the disgust which many persons have for this remedy, the saline cathartics are to be preferred. The sulphate of magnesia or soda, the Rochelle salts, or the citrate of magnesia, may be employed. The saline selected should be given in sufficient doses to produce promptly abundant dejections, and it is then to be discontinued. It will sometimes happen that after free purgation, the dysenteric evacuations do not return, and recovery at once ensues. This abortive effect takes place only in some cases in which the inflammation is not intense, and is limited in its extent. Notable diminution of the frequency of the dysenteric evacuations, and relief of the tormina and the tenesmus, not infrequently follow the operation of the saline purgative. This treatment may be pursued except in cases in which it is contra-indicated by great feebleness of the patient. In these cases castor oil is the purgative to be preferred. After intervals of a few days the saline purgative may be repeated.

Another method of effecting the removal of the contents of the large intestine deserves mention, namely, the employment of large injections. Nearly half a century ago, O'Beirne demonstrated that a flexible tube can be passed into the sigmoid flexure, and in this way a large quantity of liquid injected into the colon. He advocated the employment of this method in dysentery and other affections. Under the name irrigation (Darmeingiessungen) this method has been recently revived and recommended on the basis of clinical experience, especially by two German writers, Hegar and Mosler.[1] By means of a tube carried into the sigmoid flexure, several quarts of liquid may be injected. By the writers just named, the injection is made through a funnel elevated sufficiently for the requisite force from gravitation. The object is to remove fecal accumulations and all irritating matters. By this method, also, medicated liquids may be brought into contact with the inflamed surface. The method claims trial sufficiently to determine whether it can advantageously take the place of saline or other cathartics in the treatment of dysentery, and, also, to what extent the topical application of medicated liquids may be employed with advantage. The injections may be repeated twice or three times daily. They are made more effectual if the patient be placed in the knee-and-elbow or the knee-and-shoulder posture, but, if the patient be feeble, the decubitus may be on the back or side. Davidson's syringe will probably answer as well as, if not better than, the elevated funnel. In order to introduce as much water as is practicable and desirable, it should be introduced slowly, intermitting, from time to time, the injection for a few moments.

After purgation, opium, in some form, is the remedy to be most relied upon. A full dose of opium administered by enema, or as a suppository, will sometimes succeed in arresting the disease. It often mitigates the severity of the disease and affords marked relief. Administered by the rectum, however, it

[1] Deutsches Archiv für klin. Med., Bd. xv. p. 233, 1875.

is not always retained, and then reliance must be had upon its administration *per orem*, or hypodermically. It may be given in full doses repeated every four, six, or eight hours, or in smaller doses repeated at shorter intervals. As regards the form of opium selected, I believe this is chiefly important in respect of the preference or peculiarity of the patient. I have seen the opium in gum or powder, the various liquid preparations, and the salts of morphia equally effectual. The form found to be preferable is to be continued during the progress of the disease, the doses being regulated by the frequency of the evacuations and the suffering. Experience in each case is to be the guide as to the mode of administration. Generally the administration by the mouth and rectum alternately is advisable. The opiate remedies are to be gradually diminished as the dysenteric evacuations become less frequent, and the suffering from tormina and tenesmus is less. After two or three days, if the disease continue, the saline purgative may be repeated, if not contra-indicated by the feebleness of the patient, and afterward the use of opium resumed.

In this plan of treatment the reliance is upon free purgation and opium. The chief reliance, I believe, should be upon these measures; but other measures may be conjoined. The subnitrate or the subcarbonate of bismuth in scruple or half-drachm doses, the acetate of lead, the sulphate of copper, gallic acid, and the various vegetable astringents, such as rhatania, kino, catechu, hæmatoxylon, etc., are useful as adjuvants. These are to be relied upon, to the exclusion of opium, in those cases only in which, from a constitutional peculiarity, the latter produces unpleasant effects sufficient to preclude its employment. It is undoubtedly true that some persons are affected so unpleasantly by opium that its use is, if possible, to be avoided; but it is often the case that it is well borne in this and some other diseases, although it may not be in trivial affections. Certain preparations of opium may be well borne, although others occasion unpleasant effects. An aqueous solution or extract is frequently taken without difficulty by those who cannot comfortably take other preparations. Codeia sometimes answers a good purpose as a substitute for the preparations of opium and morphia.

Ipecacuanha has been considered a valuable remedy in dysentery. Some have attributed to it a special curative influence, and have advocated its employment in as large doses as can be borne. Maclean states that the system of treating acute dysentery, generally followed in India, is as follows: Thirty drops of the tincture of opium may be at first given, but this may be sometimes omitted and the ipecacuanha given at once. If the opiate be given, in half an hour it is to be followed by from 25 to 30 grs. of ipecacuanha. The latter remedy should be given in as small a quantity of fluid as possible, and a little syrup of orange-peel covers the taste of the medicine. The patient, after this dose, should keep perfectly quiet and abstain from fluid for, at least, three hours. With these precautions, nausea and vomiting are rarely troublesome. After eight or ten hours, the ipecacuanha may be repeated in a reduced dose, observing the same precautions.[1] If required, the treatment is to be continued for several days, the remedy being given in diminished doses, with intervals sufficient to allow mild nourishment to be taken. He cites statistics showing the mortality in India, under the use of ipecacuanha, to be 28.87 in a thousand; whereas, under the old system the mortality was 88.2 in a thousand. It is to be borne in mind, however, that the old system of treatment embraced bloodletting and the free use of mercury. I have resorted to this plan of treatment in a considerable number of cases at Bellevue Hospital, but without a very satisfactory degree of success. In a small proportion of cases the disease was either arrested or favorably modified by it; but in the ma-

[1] *Vide* article in "A System of Medicine," edited by Reynolds.

jority of cases it had no apparent influence on the disease. Dr. Woodhull, Assistant Surgeon of the U. S. Army, has reported cases showing the successful treatment of the disease by this remedy.

Mercury has been heretofore much relied upon in the treatment of this disease, given in either large doses, united with opium in order to prevent a cathartic effect, or in small doses repeated at short intervals. The recovery, in cases treated with mercury, is, of course, no proof of its value, inasmuch as sporadic dysentery tends intrinsically to recovery. The duration of the disease, the relief of the symptoms, the rapidity of convalescence, and the subsequent condition of health, are the points to be considered in estimating the influence of remedies in this disease. With reference to these points, a fair estimate of the effects of mercury has led to its rejection by most practitioners in this country as a remedy for dysentery.

During the early part of the disease, the diet should be restricted to a small quantity of the blandest articles of food. It is an object throughout the disease to keep the patient on a diet which will leave but little residuary matter to pass into the large intestine; in other words, a diet as purely nutritious as possible. After the first few days, however, it is important to provide for proper support of the system by nutritive supplies, and for this purpose milk and animal broths are best suited. If the symptoms denote failure of the vital powers, alcoholics are to be given, as in all diseases which destroy life by asthenia. Tonic remedies may be given with advantage during convalescence.

Patients should be instructed to refrain as much as possible from repeated acts of defecation and straining efforts. Cold applications to the anus sometimes relieve the tenesmus. A piece of ice may be wrapped in cloth and applied frequently in this situation. Enemas of cold water are often grateful. Relief, in some cases, is afforded by injecting astringent liquids. The nitrate of silver, a solution of tannin, acetate of lead, or the sulphate of zinc, may be thus used.

Fomentations and mild revulsive applications over the abdomen are useful as palliatives in proportion to the amount of tormina and abdominal tenderness.

Epidemic Dysentery.

Epidemic dysentery is essentially the same disease as sporadic dysentery. Certain events occur much oftener in the former than in the latter, yet there is nothing pertaining to the epidemic which is not occasionally seen in the sporadic form of the disease. Epidemic dysentery is often very fatal, yet, in the epidemics attended with the largest fatality, cases occur which are as mild as the mildest sporadic cases, and, on the other hand, occasionally in sporadic cases life is quickly destroyed. Like other diseases which prevail epidemically, this differs greatly at different times and places as regards gravity, and at certain times and places it presents features which it does not present at other times and places. The differences between the epidemics of this disease are in a measure to be explained by the co-existence of other diseases, and by the conjoint operation of morbific causes not standing in a special relation to the production of this affection. In treating of epidemic dysentery, the main object will be to point out the circumstances in which it is apt to differ from sporadic dysentery.

With respect to the anatomical characters, they are essentially the same as in cases of sporadic dysentery. In fatal cases of either form, the varied appearances which have been stated may be found. Extensive and disorganizing changes oftener occur in epidemic dysentery. As a rule, in the

latter the inflammation extends over a larger portion of the large intestine, and it sometimes extends into the ileum. Ulcerations and diphtheritic exudation are much more apt to occur in epidemic dysentery. Perforation of the intestine is sometimes a result of ulceration, giving rise to peritonitis. Perforation of the cæcum may take place in this disease, leading to abscess in the areolar tissue beneath the peritoneum, or fecal abscess. Perforation of the rectum and fecal abscess in that situation have been known to occur.

The clinical history of epidemic, differs from that of sporadic, dysentery according to differences as regards the extent and severity of the local affection, and also according to various morbid conditions due to the action of accessory causes, the latter oftener co-operating in epidemic than in sporadic cases. Severe cases of epidemic dysentery are characterized by the occurrence of sero-sanguinolent dejections, the *lotura carnium* of the older writers, containing usually pseudo-membranous and necrotic particles in more or less abundance, and holding in solution a large quantity of albumen. Hence, epidemics of dysentery are popularly known as *bloody flux*. Dejections of this character always denote gravity of disease. Tormina and tenesmus may be less prominent as symptoms in severe cases of epidemic, than in most cases of sporadic, dysentery. In some fatal cases these symptoms are entirely wanting. Tenderness over the tract of the colon may, or may not, be marked. The local symptoms in some cases of epidemic dysentery are comparatively slight, and in general, so far as my observation goes, patients suffer far less in fatal cases than in sporadic cases wholly devoid of danger. Nausea and vomiting occur oftener in the epidemic than in the sporadic disease. In epidemic dysentery albumen and casts in the urine are occasionally observed.

The differences, as regards the general symptoms, in different epidemics and different cases, are marked. Severe cases are characterized by prostration, feebleness of the circulation, coldness of the surface, in short, by symptoms denoting adynamia. The pulse may become frequent, small, soft, vibratory but compressible, or it may be small, weak, thready, with but little, and sometimes not any, increase of frequency. These characters of the pulse, denoting feebleness of the action of the heart, together with other adynamic symptoms, are developed in some cases early in the disease, without having been preceded by active febrile movement, but in other cases the pulse for a time is full and strong, the skin hot, the adynamia succeeding these symptoms of high fever. In fatal cases, a condition analogous to the stage of collapse in epidemic cholera may precede, for a variable period, the termination of the disease. In this condition the pulse is scarcely appreciable, or it is extinct, the surface is cold, and either dry or bathed in perspiration, the teeth are sometimes covered with sordes, the quantity of urine is greatly diminished, cramps of the muscles of the lower extremities sometimes occur, and this collapsed condition may exist for one, two, or three days before death. The mode of dying is by slow asthenia.

The intellect generally either remains intact, or slight mental aberration only occurs in the latter part of life. But some cases are characterized by delirium. The patient talks incoherently under the influence of transient delusions; he may attempt to get out of bed, and require to be restrained. In a case which came under my observation, the delirium was of a boisterous, mirthful character, the patient singing snatches of humorous songs, shouting, and attempting to get out of bed, after the pulse had become extinct, and the surface of the body was cold like that of a cadaver. In this case, the manifestations of delirium were so painfully incongruous, that the patient was kept under the influence of chloroform for several hours before his death.

The delirium and other symptoms, in some cases, are analogous to those

belonging to typhus and typhoid fever. The typhoid state may exist in cases of this disease as of various other affections. But it is to be borne in mind that dysentery sometimes occurs as a local complication of typhus and typhoid fever. Certain epidemics of these fevers are characterized by the occurrence of this complication. The distinction between dysentery with typhoid symptoms, or typhoid dysentery, and typhus or typhoid fever with a dysenteric affection developed secondarily, is the same as between typhoid pneumonitis and typhus or typhoid fever complicated with pneumonitis. The symptoms of scorbutus are associated with those of dysentery when, as is sometimes the case, the latter prevails among persons who are suffering from scorbutic deterioration of the blood. So, in districts where periodical fevers prevail, epidemics of dysentery may be characterized by periodicity as regards febrile movement, etc., due to the union of dysentery with intermittent or remittent fever, or the conjoined operation of the special cause producing the latter.

The duration of the disease in cases of epidemic dysentery is very variable. In malignant epidemics, the disease sometimes runs very rapidly to a fatal issue, the collapsed condition occurring perhaps in the course of a few hours. On the other hand, cases may be protracted to the third and fourth week before either convalescence or death takes place. As already stated, different epidemics differ widely as regards the severity of the disease. In some epidemics, the majority of cases are mild and the rate of mortality is very small; but in other epidemics the proportion of deaths is very large. The latter are justly distinguished as malignant. There are few epidemics more to be dreaded than those of malignant dysentery. They occur much oftener in tropical than in temperate climates, but there is no part of the world exempt from their occasional occurrence. It is one of the scourges of camps in time of war, especially if, to causes operating particularly on armies, tropical influences be added. It prevailed to a very great extent in the late civil contest in this country, among the national and the insurgent forces, especially in the Southern States, and it was often associated with phenomena referable to malaria.[1]

Epidemic dysentery is an infectious disease, the special cause produced generally, if not always, without the body; that is, it is a miasmatic infectious disease. The special cause is probably the same in epidemic and in a certain proportion of the cases of sporadic dysentery. Inflammation, however, of the large intestine may give rise to the characteristic dysenteric dejections, without the action of this special cause. The various agencies which appear to give rise to the disease, such as exposure to atmospheric vicissitudes, fatigue, and other hardships incident to army life, insufficiency of diet, over-crowding, malaria, etc., probably act as co-operating causes, rendering the system more susceptible to the dysenteric poison and giving rise to other morbid phenomena than those which the special cause would alone produce. Epidemics would perhaps not often occur were it not for the operation of accessory causes; hence the rationale of their occurrence in camps, in prisons, and in situations where numbers are exposed to hygienic influences conducive to the development of any disease. With respect to the source of the special cause of dysentery, or the conditions under which it is generated and diffused, we have at present no positive knowledge. The contagiousness of epidemic dysentery has been a much mooted question. Without entering into any discussion of this question, I shall content myself with saying that this is probably one of a group of diseases, the evidence of the communicability of which rests mainly on the successive occurrence of a greater or less number

[1] *Vide* Woodward, Second med. volume of Med. and Surg. History of the War of the Rebellion.

of cases among members of one household, or persons who, from proximity of residence, are brought into contact with each other; and the diffusion of the disease, under these circumstances, may be satisfactorily accounted for by the fact that the persons attacked are alike exposed to the special cause, together with the same co-operating causes. It is, however, proper to state that some distinguished authors suppose that the intestinal excreta contain a virus by means of which the disease may be communicated. Whether the disease be communicable or not, there are instances which seem to afford evidence that the special cause may be transported by means of clothing, etc.

The opinions of different writers and practitioners concerning the treatment of dysentery, especially as an epidemic, show great diversity, and there is abundant testimony of the success of measures quite opposite in character. The fact just stated shows, either that the recoveries were due mainly to an intrinsic tendency of the disease, or that the disease is presented at different times and places under different pathological phases, and the measures of treatment require to be correspondingly varied. Both explanations are doubtless measurably applicable. Sporadic dysentery, as a rule, and epidemic dysentery in a certain proportion of cases, tend intrinsically to recovery. Recovery, under these circumstances, takes place, whatever be the treatment, provided it be not destructive. On the other hand, in a certain proportion of cases of epidemic dysentery, the disease must, of necessity, end fatally. The extent of mucous surface affected, the loss of fluids by hemorrhage and transudation, and the destructive lesions which take place, preclude recovery under any treatment. But it is also true that the different features which the disease assumes in different epidemics, and the various morbid conditions with which it may be associated, must influence, more or less, therapeutical measures.

Purgatives, especially of the saline class, may be as appropriate in epidemic as in sporadic dysentery; but they should be given cautiously or omitted if sero-sanguinolent dejections occur or if the symptoms denote much tendency to adynamia. Theoretically it would seem that the removal of the fecal contents of the intestine would be more safely effected by large injections (irrigation) than by saline purgatives. It is immensely desirable to arrest or moderate the dejections just named, for these doubtless conduce to the condition of collapse into which patients are apt to fall. For this purpose, opium is to be given in as large doses as are required or as are well borne, in conjunction with astringent remedies, such as gallic acid, acetate of lead, the persulphate or pernitrate of iron, rhatania, etc. I believe the main reliance should be placed on opium, in some form, in these cases, other remedies being considered as auxiliary. The latter, therefore, are not to be employed as substitutes for opium except in cases in which, from a constitutional peculiarity, this remedy, in any form, produces such distressing effects as to preclude its use. It should not be decided that opium cannot be tolerated on the assertion of the patient, but only after a fair trial.

In this disease, as in some others, there is frequently a wonderful tolerance of opium, a tolerance not to be explained by the antagonizing influence of pain, since it is manifested in cases in which pain is not a prominent symptom. Christison, in stating this fact, adds that he has known from 24 to 30 grains of the gum of opium to be taken in the course of 24 hours. I have given 2 grains hourly, in the case of a female affected with dysentery characterized by abundant sero-sanguinolent dejections for the space of a week, and without, at any time, symptoms denoting narcotism. I have met with a case exemplifying a still greater tolerance of this remedy. In this case, the patient not being habituated to the use of opium before his illness, the quantity of the sulphate of morphia, given hourly, was gradually increased to one grain, mak-

ing 24 grains in the 24 hours, and this quantity was given for several consecutive days without any narcotism. Opium is not to be given as a matter of course in doses approaching these, but it is to be given with a view to the desired end, namely, the arrest of the sero-sanguinolent dejections; and if this effect be not obtained, the doses are to be increased to the amount which will be borne without narcotism, be the amount never so large. It is hardly necessary to say that, in increasing the dose, the condition of the patient is to be carefully watched; attention is to be directed to the pupils, and to the number of respirations, as well as to the soporific state, in order to avoid a cumulation which may result, unexpectedly, in narcotism. The quantity of opium which may with prudence and propriety be given in dysentery, will vary greatly according to the varying tolerance in different cases.

In proportion as the symptoms denote a tendency to death by asthenia, the powers of life are to be supported by alcoholics and nourishment. The general principles which should govern the employment of supporting measures are the same as in other affections which, in like manner, tend to destroy life by exhaustion. Alcoholics are sometimes tolerated in large quantity in severe cases of this disease. I have known over 40 ounces of brandy to be taken in 24 hours by a patient who, in health, was not accustomed to the use of ardent spirits, and this large quantity produced no excitation of the circulation or nervous system. This patient was apparently saved by the persevering use of alcohol with large doses of the sulphate of morphia. I have repeatedly seen patients recover under the vigorous employment of supporting measures, conjoined with opium in large doses, when, as judged by the symptoms, the condition appeared to be truly desperate. Yet, of the cases properly distinguished as malignant, many must die, despite the faithful employment of the measures on which the chief reliance is to be placed.

Dysentery associated with phenomena denoting the operation of the special cause of periodical fever, calls for treatment having reference to the latter, in addition to the measures addressed to the dysenteric affection. Quinia is a highly important remedy in these cases. Associated with scorbutus, the dietetic and remedial measures appropriate to this condition are indicated. Occurring as a complication of the continued fevers, it furnishes an additional indication for the supporting measures which these fevers claim irrespective of the dysenteric complication. Co-existing rheumatism calls for the addition of the remedies appropriate for this disease.

Chronic Dysentery.

The anatomical basis of chronic dysentery is chronic inflammation of the large intestine with or without ulceration. The term, however, is sometimes applied to cases of functional diarrhœa, and, on the other hand, the term chronic diarrhœa is often applied to cases of chronic dysentery. The distinction between chronic diarrhœa and chronic dysentery is usually based upon the character of the stools. It is impossible, however, to draw a sharp boundary line between the two processes. Woodward even takes the ground that no distinction is admissible. He says:[1] "The results of any attempt to subdivide these cases into chronic diarrhœa and chronic dysentery, in accordance with the presence or absence of tenesmus, or of mucus, muco-pus, pus, or blood in the stools, or any other clinical evidence with which I am acquainted, would not be found to correspond with any anatomical classification." He therefore includes under the name chronic dysentery all the chronic alvine

[1] Woodward, 2d med. vol. of the Med. and Surg. History of the War of the Rebellion, p. 483, Washington, 1879.

fluxes with the exception of those resulting from tuberculous ulceration of the intestine. But, as in many other processes which cannot be sharply separated from each other, it is here convenient to retain the old names, although the assignment of certain cases to one class or to the other may be more or less arbitrary. Typical cases of chronic diarrhœa, however, are sufficiently well distinguished from typical cases of chronic dysentery.

Chronic dysentery very rarely occurs in this climate, save as a sequel of acute dysentery; recovery from the latter does not take place, but the inflammation becomes chronic, or, more commonly, ulcerations which take place during the acute affection do not cicatrize, but continue for an indefinite period. Acute exacerbations often occur in the course of chronic dysentery. Acute dysentery, however, very rarely eventuates in the chronic form of the disease in temperate climates, and hence chronic dysentery is rare in these climates. It is otherwise in warm climates. Here the chronic often follows the acute affection. Chronic dysentery in tropical climates may also begin insidiously without an acute attack. Chronic dysentery thus prevails chiefly in tropical countries, or among those who have contracted dysentery in these countries. In the Northern States of the Union, the cases observed are, for the most part, imported from the South. Of the soldiers who returned from the war in Mexico, large numbers were affected with this disease; and, during the late civil war, cases were abundant among the soldiers sent to the northern military hospitals from different points in the Southern States.

The lesions observed in chronic dysentery are the result of inflammation of the mucous and submucous coats of the large intestine, with or without ulceration. Chronic inflammation without ulceration presents an appearance in many respects similar to that already described for acute simple inflammation of the large intestine. Instead of bright red, the color of the mucous membrane is more frequently bluish-red, or some hue due to the deposit of dark pigment, as brown, slate-color, ash-color. The pigmentation may be both in the follicles and in the mucous membrane outside of the follicles. The mucous and submucous tissues are thickened, usually more in some places than in others. The wall of the intestine often feels stiff and hard. Its calibre may be diminished. The mucous membrane may present many small elevations lying close to each other and producing the so-called mammillated appearance. In rare cases large polyp-like excrescences, consisting of hyperplastic connective tissue containing glands and covered with columnar epithelium, are produced, and may be present in large number (enteritis polyposa). Sometimes little projecting cysts, varying in size from a pin's head to a pea, and containing clear mucus, are observed beneath the mucous membrane. These are formed by the dilatation and coalescence of the tubules of Lieberkühn. They generally occupy the site of the solitary follicles. As pointed out by Cornil, and especially by Kelsch,[1] the solitary follicles in dysentery, particularly in cases with follicular enlargement and ulceration, are not infrequently invaded by distension and new growth of the adjoining tubules of Lieberkühn. The thickening of the mucous and submucous coats in chronic dysentery is due partly to infiltration with new cells and partly to new formation of connective tissue. There is, however, less tendency toward the development of new fibrillated connective tissue in chronic dysentery than in the chronic inflammation of most mucous membranes. Hence, complete recovery is possible after long duration of the disease. In some cases of chronic dysentery, enlargement and ulceration of the solitary follicles are very prominent, and constitute almost the sole lesions. Such cases are called follicular inflammation or follicular dysentery. In many of these cases the growth of

[1] Kelsch, Archives de Phys. norm. et path., 1873, pp. 406 and 573.

the glands of Lieberkühn into the follicles has been observed by Kelsch and by Woodward. Swelling and ulceration of the follicles, however, frequently occur without any such growth.[1]

The ulcers which may occur in dysentery are of three kinds: first, follicular, second, non-follicular or simple (catarrhal), and, third, diphtheritic. These varieties are often combined. The follicular ulcerations are the result of softening and breaking down of the swollen solitary follicles, either in their centres or in their apices. The ulcer at first presents a little round constricted opening, as if punched out, leading into an irregular cavity in the submucous tissue. It extends peripherally more rapidly in the submucous than in the mucous coat, and hence often presents overhanging edges, even when of considerable size. By extension and coalescence of these follicular ulcers, large losses of substance in the inner coats of the intestine are produced. Ulcers unconnected with the follicles are formed by dense infiltration of the mucous membrane with pus-cells. By softening and molecular disintegration of the intercellular substance, first in the upper layers, superficial ulcers are produced. These extend in depth and in superficies by continuance of the purulent infiltration and by liquefaction of the basement substance. These ulcers possess no very distinctive characters. They resemble closely those produced by diphtheritic sloughing. The method of formation of diphtheritic ulcers has already been sufficiently described under the head of acute dysentery. When the fibrinous exudation and sloughing process disappear, these ulcers extend by the same process of suppuration as the preceding. They usually present abrupt or sloping edges, but may have undermined walls. In fact, when dysenteric ulcers attain to a large size, it is generally impossible to tell in what way they have originated. Any of these ulcers may extend in depth so far as to perforate the intestinal wall, but this is a rare occurrence. Recovery from dysentery with ulceration is effected by cicatrization of the ulcers. Some ulcers may cicatrize, while others are extending. There is nothing characteristic regarding these cicatrices except in the case of those resulting from small follicular ulcers. The cicatrices of these small follicular ulcers are stellate in shape. The radiating ridges extend into the substance of the surrounding mucous membrane, and inclose between them mucous membrane somewhat modified, but containing the glands of Lieberkühn (Woodward). Allusion has already been made to the occasional occurrence of stricture of the intestine from contraction of the cicatrices resulting from dysenteric ulcers. Waxy degeneration of the intestinal mucous membrane has been occasionally observed in cases of dysentery. Acute diphtheritic inflammation may occur at any time during the course of chronic dysentery, and may lead to a fatal issue. Of the diseases which may complicate chronic dysentery, peritonitis, hepatic abscess, and pneumonitis should be mentioned especially. Abscess of the liver is a frequent complication in tropical, but rare in temperate, climates. It is generally in the form of small multiple abscesses.

In chronic dysentery the evacuations vary considerably in character. They

[1] Kelsch (loc. cit.) describes a form of dysentery, prevalent in tropical countries, in which embryonic or granulation-tissue develops in the mucous membrane and obliterates most of the glands of Lieberkühn. Portions of these glands undergo cystic distension and invade the solitary follicles. Embryonic cells collect in especially large number about Brücke's muscle and infiltrate also the submucosa. The disease begins insidiously, and, unless acute attacks occur, no ulceration takes place. If there be an acute attack, the accumulation of pus-cells about the vascular plexus beneath the mucous membrane becomes so great as to shut off the nutritive supply to the tissue above, and gives rise to sloughing of the mucous membrane. Kelsch denies that a fibrinous or diphtheritic exudation ever occurs in dysentery, but his observations are based upon an insufficient number of cases.

contain at times thin or pultaceous feces, and occasionally scybala. Their most characteristic ingredients are mucus, pus, and blood. Flakes of pseudo-membrane and of necrosed tissue are present only when an acute diphtheritic inflammation supervenes. Undigested particles of food are often present, especially when substances difficult of digestion are taken. Woodward applies the epithet yeasty to frothy stools containing bubbles of carbonic acid and the yeast fungus. These may be observed when the digestion is greatly impaired and amylaceous articles of food are taken. The stools are usually accompanied with griping pains. Tenesmus is less frequent than in acute dysentery. In some cases the evacuations are unattended with any feeling of distress. The stools vary from three or four to twenty or more in the twenty-four hours. There may be intervals in which constipation takes the place of the frequent discharges. The accumulation of gas in the intestine and the escape of flatus may be annoying symptoms. In severe cases the stools are always loose and thin, and contain mucus, pus, and blood. In these cases it is to be inferred that the inflammation extends over the whole or the greater part of the large intestine. In other cases, dysenteric discharges occur more or less frequently in alternation with fecal dejections. In these cases the inflammation is less diffused. If the evacuations be generally or frequently solid or moulded, the dysenteric evacuations being superadded, the inflammation or lesions are circumscribed and situated near the anus. In these cases, ulcerations may sometimes be seen, if examination be made with the speculum. There is generally more or less abdominal tenderness along the line of the colon.

Chronic dysentery is one of the most intractable and hopeless of diseases. For a time, if the evacuations be held in check by palliative measures, the appetite and digestion not being greatly impaired, the general aspect and strength may not show much deterioration, but at length the appetite and digestion fail, and the continued irritation and loss of fluids induce progressive emaciation and debility. The duration of the disease embraces usually several months, and sometimes years. If not destroyed by some intercurrent affection, the patient becomes extremely emaciated, reduced almost to a skeleton, the surface is usually dry, cool or cold, the pulse becomes more and more feeble; the mental faculties are weakened, delirium rarely occurring, but the mind, in certain cases, falls into an apathetic state, the patient being indifferent to, and taking but little notice of, persons and things around him. Anorexia becomes complete, and vomiting, in some cases, is a prominent symptom; œdema of the lower limbs sometimes occurs; ulceration of the cornea is an occasional event, and I have known the cornea to be perforated, with loss of the humors of both eyes. The mode in which a fatal termination takes place is generally typical of dying by slow asthenia. The immediate cause of death is sometimes general peritonitis from perforation of the intestine. Parenchymatous nephritis is a not infrequent complication, but uræmic coma and convulsions are rare. Woodward states that "sudden death was a not infrequent occurrence, and attracted considerable attention during the war."[1]

The diagnosis of chronic dysentery is not altogether easy. The disease is to be discriminated from functional diarrhœa, and this is not always readily done. The presence of pus, mucus, and blood at times, if not frequently or constantly, is the important point in the differential diagnosis. It is also to be discriminated from ulceration of the large intestine due to tuberculosis, or carcinoma, or other causes. Tuberculosis may be excluded if the lungs be free from the deposit of tubercle. In carcinomatous disease, frequently a tumor is to be felt through the abdominal walls, or if seated in the rectum it

[1] Op. cit.

is accessible to examination by means of the touch and speculum. The fact that chronic, in the great majority of cases, is preceded by acute dysentery, is highly important in the diagnosis. We may conclude at once that the disease is chronic dysentery if it have followed the acute disease, and the latter fact may generally be without difficulty ascertained, owing to the well-marked diagnostic symptoms of acute dysentery. In temperate climates the affections with which chronic dysentery is liable to be confounded are most likely to exist in cases of doubt, owing to the great infrequency of the latter.

The treatment of chronic dysentery relates, *first*, to the local affection. Remedies to allay irritation and to promote the healing of ulcerations are indicated. But, unhappily, in the great majority of cases, there is very little probability that a cure will be effected, and all that can be hoped for from judicious treatment are palliation of symptoms and prolongation of life.

Certain remedies have been employed with a view to their direct action upon the affected portions of the intestines. The nitrate of silver is one of these; but it is absurd to suppose that this remedy, given as largely as prudence will allow, passes through the stomach and small intestines unchanged. Whatever benefit may be derived from it, therefore, is not to be explained on the ground of its topical application to the diseased surface. The balsamic medicines, particularly the balsam of copaiba, have been given for the same purpose, and with more reason; but clinical observation shows not much benefit to be derived from them. The subnitrate or the subcarbonate of bismuth may be included among the remedies supposed to act by coming in contact with the affected parts. This remedy is often beneficial as a palliative, the dejections becoming less frequent, with relief of pain, etc., under its use. It should be given in doses of from 20 to 30 grains three or four times daily. Some have recommended much larger doses, and, given almost without limit, it produces no deleterious effects; but probably all the benefit to be derived from it is secured by the doses just stated. Its administration in enemas has been advocated in this disease. The various astringent remedies are to be tried in succession. Of those most likely to be useful, the following may be mentioned: tannic or gallic acid, alumen, rhatania, rubus villosus (blackberry-root), and the persulphate or pernitrate of iron. The oxide of zinc is considered by many as a useful remedy.

In so far as the dejections are controllable by the foregoing remedies, they should be relied upon to the exclusion of opium, because they will interfere less with appetite and digestion. Opiates, however, will be required, to a greater or less extent, in conjunction with other remedies. So far as practicable they should be administered by the rectum, either in enemas (a salt of morphia, or some liquid preparation, contained in an ounce of mucilage or thin starch-water), or in suppositories. The lower part of the rectum should be examined with the speculum, and appropriate topical applications made if ulcers in this situation be discovered. Dr. Maury and Prof. T. G. Thomas have reported cases in which remarkable benefit followed the application of nitric acid to ulcerations within the rectum, and they call attention to the fact that by means of a speculum the interior of the bowel may be brought into view as far as the sigmoid flexure.[1] The removal of fecal collections and other irritating material by means of large injections given through a flexible tube introduced into the sigmoid flexure, deserves trial in chronic, as in acute, dysentery. Prudence, however, dictates caution in the introduction of the tube, and as regards the quantity of water introduced, lest rupture at an ulcerated spot may be produced.

[1] *Vide* New York Med. Journ., Jan. 1876, and the Author's Clinical Medicine, page 292 *et seq.*

The treatment relates, *secondly*, to the system. In relative importance, the general take precedence of the local measures. The surface of the body should be well protected against atmospheric changes. The diet should be nutritious but bland, articles of food being selected which do not leave much indigestible matter to pass into the large intestine. Milk, eggs, and farinaceous food are generally best suited, but in some cases animal food is found to agree. The plan of diet is to be governed by experimental trials. Tonic remedies and alcoholic stimulants are indicated by defective appetite and digestion. Of tonic remedies, quinia, the chalybeate preparations, the mineral acids, and the bitter infusions are to be employed in succession. The use of alcoholic stimulants is to be regulated by their effects in individual cases. Moderate out-of-door exercise and mental recreation are important. Change of climate is sometimes effectual when other measures prove unavailing. The experience of the late war showed the happiest effect of transferring soldiers from the South to northern hospitals in salubrious rural situations.

Inflammation and Perforation of the Cæcum. Fecal Abscess.

Inflammation of the cæcum, the inflammation limited to this portion of the large intestine, constitutes an affection called *typhlitis*, *tuphlo-enteritis*, or *cæcitis*. Acute inflammation confined to the cæcum is not of frequent occurrence. The symptoms are, pain and tenderness within a circumscribed space corresponding to the situation of the cæcum, with vomiting, diarrhœa, and febrile movement. It is liable to be confounded with phlegmonous inflammation connected with disease of the vertebræ, renal calculus, circumscribed peritonitis from perforation of the vermiform appendix, and inflammation of the right ovary. Peritoneal inflammation, limited to the portion of peritoneum covering the cæcum, may accompany the affection. The pain and tenderness are then more marked, and the cæcum is distended by an accumulation of gas, the peritoneal inflammation producing paralysis of the muscular tunic. The distension sometimes is so great that a circumscribed prominence corresponding to the area occupied by this portion of the large intestine is manifest to the eye, and felt through the abdominal walls. Diarrhœa is not uniformly present. Extension of the limbs may occasion pain, as in cases of general peritonitis. The cases which I have seen have terminated in recovery. I have not met with perforation followed by either general peritonitis or fecal abscess in a case of acute inflammation of the cæcum. The probable explanation is that, in these acute cases, circumscribed peritonitis gives rise to an agglutination of peritoneal surfaces, which is protective against perforation. Subacute inflammation gives rise to symptoms less distinctive. It may occur, and recovery take place without the development of symptoms denoting an affection of importance; but it becomes a very important affection when it leads to ulceration and perforation of the intestinal coats. If the perforation take place in that portion of the cæcum not invested with the peritoneum, the gaseous and other contents of the intestine, escaping into the areolar tissue, give rise to inflammation which may be either diffused or circumscribed, in the latter case forming an abscess called a fecal abscess. If diffused, the inflammation may extend more or less over the abdominal walls, which become swelled, pitting on pressure as in œdema, with a feeling of crepitation due to the permeation of intestinal gas. If an incision be made, a dark, sanious liquid escapes with gas emitting an intestinal odor. Under these circumstances, a fatal result is inevitable. If, however, the perforation lead to a circumscribed abscess which opens externally, gas and fecal matter, with pus, escape, a fistulous communication with the intestine is

established, and this may remain permanently, or it may gradually close and recovery take place.

Perforation at a point where the intestine is covered with the peritoneum may give rise to diffuse peritonitis which, in most cases, if not invariably, is fatal. Often, however, the escape of the intestinal contents into the peritoneal cavity is prevented by a prior circumscribed peritonitis resulting in protective adhesion of the peritoneal surfaces. Under these circumstances, a perityphlitic abscess follows, and this is liable to rupture into the peritoneal cavity if timely surgical interference be not resorted to. As regards diagnosis, fecal or perityphlitic abscesses are to be discriminated from psoas abscess in Pott's disease, abscess with caries of pelvic bones, cellulitis, abscess originating in the abdominal wall, and diseases of the hip-joint. Tympanitic resonance on percussion and crepitation from the presence of intestinal gas are diagnostic points.[1]

The causes of inflammation of the cæcum, whether acute or subacute, are, probably, the detention in this situation of the feces, and the presence of irritating matters either received with the ingesta, or arising from chemical changes within the intestine. Over-exercise and exposure to cold may be auxiliary causes.

Complete rest is an essential part of the treatment. This should be rigidly enforced when the inflammation is subacute, not less than when it is acute. The importance of this part of the treatment relates to the prevention of perforation. It is desirable to effect the removal of the contents of the cæcum, but active purgatives are fraught with danger. Mild laxatives only are admissible, such as castor oil or small doses of Epsom salts. It is, perhaps, safest to rely upon enemata given through a long flexible tube carried upward to the sigmoid flexure. These may be repeated at short intervals, that is, three or four times daily. A warm poultice or the water dressing should be applied over the site of the cæcum. Blisters and other counter-irritant applications are of doubtful utility. The ingesta should be restricted to animal broths and milk with the addition of lime-water. Opiates should be given in doses sufficient to relieve pain. After the disappearance of the symptoms denoting inflammation, the diet, for some time, should be regulated with reference to a small quantity of fecal residue; the bowels should be kept soluble by mild laxatives, and physical exercise should be interdicted.

Perforation of the cæcum from an ulcerative process may take place without having been preceded by local symptoms denoting any important affection. It occurs perhaps when patients are engaged in their usual avocations. A localized sharp pain is usually felt at the time of the perforation, followed by circumscribed tenderness. These symptoms should excite at once suspicion. Within the area of the pain and tenderness, situated in the right iliac fossa, a sense of resistance is shortly felt by the touch, the boundaries of which may not be sharply defined. On percussion there may be either flatness or a tympanitic resonance; the latter, if limited to the area of tenderness, being due to gas escaping through the perforation. In the course of a few days fluctuation is appreciable.

The diagnosis of fecal abscess following perforation rests on the foregoing points. The tympanitic resonance, if ascertained not to be transmitted from the cæcum, distinguishes this abscess from phlegmonous suppuration which is primarily extra-cæcal, that is, not secondary to perforation. An abscess, however, originating in either the connective tissue behind the cæcum or in the abdominal wall, may lead to perforation of the intestine. In the latter

[1] *Vide* an analysis of thirty-two cases, by Prof. Roberts Bartholow, in the Amer. Journ. of Med. Sciences, Oct. 1866.

case, if the abscess do not discharge its contents into the intestine and a fluctuating tumor remain, the differential diagnosis is not important practically, since the treatment indicated is the same as if the perforation preceded the abscess.

An abscess connected with perforation of the cæcum, if treated only by rest, fomentations, and anodyne remedies, may open externally, as already stated, and recovery follow. The recovery may be rapid, as in an instance which I have reported.[1] The discharge may take place into the intestine, and recovery follow closure of the perforation. An opening may take place into the bladder, and fecal matter be passed with the urine. I have met with an instance of this kind. There is, however, danger of the discharge of pus into the peritoneal cavity, and consequent fatal peritonitis. The pus is rarely absorbed.

The treatment which has proved successful in the hands of many surgeons in this country is that inaugurated by Prof. Willard Parker in 1867. It consists in removing the pus, either by aspiration or by a free opening, as soon as fluctuation is felt and the presence of pus demonstrated by an exploratory puncture. This method is a highly important improvement in the treatment of perityphlitic or fecal abscess. Further details belong to surgery.[2]

Absolute rest is to be enjoined until recovery; cathartics are to be avoided, and the patient should be restricted to a purely nutritious diet.

Inflammation and Perforation of the Vermiform Appendix of the Cæcum.

The appendix is, in fact, a part of the cæcum, but inflammation and perforation here may occur independently of any affection of the cæcum proper. The term typhlitis is applied to inflammation of the vermiform appendix as well as to cæcitis. Perforation of the cæcum is much more infrequent than of the appendix.

Acute inflammation of the appendix gives rise to a tumor which was described by James Jackson, in his "Letters to a Young Physician," under the name "A painful tumor near the cæcum." Jackson described the pain and tumor as seated on a horizontal line connecting the two anterior superior spinous processes of the ilium, at the point where this line intersects the right margin of the rectus muscle on the right side. The tumor is not superficial, but is felt on deep percussion through the abdominal wall. Marked tenderness on pressure exists within a circumscribed space over the tumor. In several cases detailed by Jackson the pain and tenderness, together with the tumor, slowly disappeared under treatment with cathartics, leeches, a blister to the part, and opium to relieve pain. He confessed his inability to form an opinion as to the precise seat and character of the affection. I have met with cases corresponding to those which he described, and it seems to me clear that they are cases of acute inflammation of the appendix. In none of the cases under my observation has perforation occurred, and none have ended fatally.

Inflammation of the appendix is probably caused either by the entrance of irritating substances within its cavity or by distension from fecal matter. The communication of its cavity with that of the cæcum becomes closed, and dilatation results from the accumulation of inflammatory products. It may be dilated to form a tumor of considerable size. According to Virchow, the

[1] *Vide* Clinical Medicine.

[2] For a table of sixty cases, with operations and results, collected by Dr. William C. Wey, *vide* Trans. of the State Med. Soc. of New York, 1880.

tumor may be as large as a man's fist. Instances of a tumor of this size must be extremely rare. The localization and description by Jackson cannot be improved upon.

It is not easy to understand why perforation from ulceration or sloughing should not often occur in connection with acute inflammation and considerable dilatation, excepting by supposing that protection is afforded by circumscribed peritonitis and adhesions therefrom resulting.

The treatment is the same as in cases of acute typhlitis (*vide* page 428). Cathartics, although employed by Jackson, involve danger by preventing adhesion.

Perforation, without the evidence of acute inflammation, is of not infrequent occurrence.

Perforation of the appendix is usually not preceded by symptoms denoting acute inflammation. In the cases which have come under my observation, the patients generally had had uncomfortable sensations in the iliac region for two or three days, and in many instances had taken some cathartic medicine thinking that they were "bilious" or needed "clearing out." Suddenly a sharp, lancinating pain forced them to seek medical advice. In a short time were developed the symptoms of a diffuse peritonitis which, under these circumstances, proves fatal as a rule, with perhaps a few exceptions. At the autopsy, generally, within the appendix hard bodies are found, to which it is customary to attribute the perforation. These bodies are usually of small size (from a pea to a date-stone), and consist of hard feces, a calcareous material, the seeds or stones of fruit, etc. If nothing be found, the supposition is that the bodies have escaped through the perforation. It is difficult to understand why these bodies should occasion perforation, but the frequency with which they are found in these cases seems to render probable their agency; and also the fact that in the great majority of cases the perforation is produced by ulceration, and not by sloughing.

In the exceptional instances of recovery, when diffuse peritonitis has been thus induced, the appendix quickly becomes adherent to adjacent parts, and the perforation is in this way closed. I have met with fatal cases in which the appearances after death showed more or less progress toward this result. In the examination of bodies dead with other diseases, old adhesions are not infrequently found. They are probably results of circumscribed peritonitis, secondary to disease of the appendix, having perhaps protected against perforation. Adhesion taking place before perforation occurs, protects against diffuse peritonitis; but fecal abscess may follow, as in cases of perforation of the cæcum. I have seen a specimen in which the appendix was attached to the bladder, and perforation had taken place causing a vesico-intestinal fistula. The first evidence of this was the appearance of a lumbricoid worm at the end of the penis, the patient then being eight years of age. Subsequently other worms were discharged with the urine, and repeatedly the seeds of fruit. Most of the urine was discharged by the bowels. The fistula for many years gave but little inconvenience. The patient served as a soldier in the late civil war. He was operated upon for stone in the bladder, and died five days after the operation, the fistula having existed for twenty years.

Pain or uneasiness referred to the right iliac fossa, without other symptoms of disease, should always excite apprehension in the mind of the physician. Rest should be enjoined and cathartics avoided. By these precautions, if patients seek advice prior to perforation, its occurrence may perhaps be prevented.

Colitis. Proctitis.

Inflammation of the colon (colitis) and rectum (proctitis) furnishes the anatomical characters of dysentery. But in the latter, the inflammation is to

be usually regarded as the local manifestation of a general disease which involves a special cause; hence, some writers include dysentery among the infectious diseases, using the term infectious in the sense now generally adopted (*vide* page 89). The terms colitis and proctitis may be applied to inflammation in the colon and in the rectum when it is purely local, and due to causes acting directly upon the parts affected. These terms will then correspond to the ordinary catarrhal inflammation of many authors.

Colitis, in this scope of the term, is rarely acute; but as a subacute affection it is not rare in the adult, and is common in infancy. It enters into the disease known as cholera infantum, or the ileo-colitis of childhood. It may, or may not, be associated with inflammation seated in the small intestine (enteritis). In the cases among soldiers, grouped by Woodward under the name Acute Diarrhœa, inflammation affected especially the large intestine. The local symptoms are colicky pains, diarrhœa, the dejections being loose or watery, and containing gelatinous mucus in greater or less quantity, with absence of tenesmus, the diagnostic symptom of dysentery. Tenderness may be present, either limited to, or most marked in, the situation of the colon. The diagnosis is to be based on these symptoms. Fever, anorexia, and general debility are associated with these symptoms, and are proportionate to the degree of inflammation, its extent, and the quantity of intestinal transudation.

The causes are local, pertaining to the accumulation of feces and, more especially, to the presence of undigested irritating matters received from the small intestine. General causes, such as over-fatigue, exposure to cold, insufficient alimentation, intemperance, etc., co-operate with the local causes, increasing the susceptibility to the latter and impairing tolerance. Hence the greater frequency and the greater severity of the disease in military campaigns than in civil life.

The general principles of the treatment are essentially the same as in cases of sporadic dysentery.

There is no practical advantage in endeavoring to distinguish chronic colitis from chronic dysentery, although the distinction may be admissible on anatomical and pathological grounds.

Proctitis occurs from the action of local causes, and may simulate dysentery as regards the presence of mucus and blood in the dejections, together with tenesmus. Diarrhœa is wanting, and the clinical history, in other respects, lacks the features of a truly dysenteric disease. Perforation of the rectum sometimes gives rise to peri-proctitis and fecal abscess. These purely local affections of the rectum are properly surgical.

Reference may be made here to the occasional expulsion, *per rectum*, of membraniform casts of the intestinal tube. These have been observed a foot in length. They have been supposed to be the mucous membrane itself exfoliated, but oftener have been mistaken for fibrinous exudation. The distinction from the latter is essential. They consist of inspissated mucus, and do not contain fibrin or coagulable lymph. Their expulsion is preceded and accompanied by colicy pains and diarrhœa, the dejections containing blood and muco-pus. In most instances the casts are expelled repeatedly after variable intervals. The patients are generally women who manifest hysterical phenomena, and uterine troubles are often associated.

The casts, probably, are formed in the large intestine, and, in connection with other symptoms, denote inflammation. The affection is thus a variety of colitis. It has received a variety of names. Da Costa, who has reported a number of cases,[1] calls it membranous enteritis. The name tubular diar-

[1] American Journal of the Medical Sciences, Oct. 1871.

rhœa was proposed by John Mason Good, and to this name Woodward gives the preference, as implying no theory. The reader is referred to the Medical History of the War of the Rebellion (p. 363) for a full reference to the literature of this curious intestinal affection.

CHAPTER II.

INFLAMMATORY DISEASES OF THE SMALL INTESTINE AND OF THE STOMACH. PHARYNGITIS. PAROTIDITIS.

Acute Enteritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Enteritis. Acute Gastritis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Gastritis. Phlegmonous Gastritis. Chronic Interstitial Gastritis. Duodenitis. Pharyngitis. Parotiditis.

Acute Enteritis.

THE term enteritis signifies literally intestinal inflammation. Various significations have been attached to it by different writers. The older writers described under this name inflammation of the serous coat of the intestine, but modern authors, almost without exception, apply the term to inflammation of only the mucous and submucous layers. Many pathologists understand by enteritis inflammation of any part of the intestinal tract, and consider as subdivisions of enteritis—duodenitis, jejunitis, ileitis, typhlitis, colitis, and proctitis. There are clinical grounds for distinguishing as separate affections duodenitis (usually in conjunction with gastritis), typhlitis, and proctitis; but it is impossible to distinguish, clinically, jejunitis and ileitis. It has already been remarked that diffuse inflammation of the large intestine is liable to involve the lower part of the ileum; it is likewise true that inflammation of the small intestine frequently extends into the large intestine. As we already have in the word dysentery a name for inflammation of the large intestine, especially inflammation of its lower part, it has become a conventional usage in this country, and to an extent elsewhere, to apply the term enteritis particularly to inflammation of the small intestine. The fact, however, is recognized that, as in dysentery, the inflammation often involves the ileum, so in enteritis, with even greater frequency, the inflammation extends to the upper part of the large intestine. It will be found that in most of the cases here described as enteritis the inflammation is most intense in the ileum, the cæcum and upper parts of the colon. The inflammation may be, however, nearly or quite confined to the small intestine.[1]

[1] Woodward (2d Med. vol. of Med. and Surg. History, etc., p. 266 *et seq.*), after pointing out the diverse conceptions of enteritis, makes use of the expression acute diarrhœa to designate what others have called acute enteritis, acute intestinal catarrh, etc. He considers acute diarrhœa as always an irritative or an inflammatory affection, and as dependent chiefly upon inflammation of the cæcum and colon. While recognizing the convenience of Woodward's classification for his purposes, it must be said that this use of the term diarrhœa as the name of a disease cannot be considered a fortunate one. Diarrhœa is a symptom; and it is not in harmony with the views of most clinical and pathological observers to regard it as dependent upon a single pathological condition. The whole tendency of modern medical nomenclature is to substitute anatomical for symptomatic names of diseases.

Anatomical Characters.—As the disease in itself rarely proves fatal, the opportunity of inspecting the appearances after death is not often offered. The changes are essentially the same as those described for acute simple inflammation of the large intestine (p. 408). The mucous membrane presents an arborescent redness, either diffusely or in patches. Ecchymoses within and beneath this membrane may be observed. Its surface is coated with mucus and muco-pus. An increased transudation of serum occurs, which, combined with rapid peristalsis, causes fluid stools. The mucous and submucous tissues are swollen, in consequence of œdema, congestion, and cell-infiltration. The enlargement of the villi gives a plush-like appearance to the surface of the mucous membrane. The solitary and agminated follicles usually are swollen, and appear as grayish-white elevations surrounded by a red congested zone. The microscopical examination shows a variable number of emigrated white blood-corpuscles in the submucous and mucous coats. The same remarks are applicable to the desquamation of the epithelium here as in acute simple inflammation of the large intestine.

Clinical History.—The local symptoms, in cases of acute enteritis, are pain, tenderness on pressure over the abdomen, especially over the lower part of the ileum and the cæcum, and, frequently, diarrhœa, with nausea and vomiting. The pain is not intense, and is of a dull, aching character, with exacerbations in which it resembles the pain of colic. The pain is referred to the umbilical region. The tenderness is not great. Slight pressure is well borne, but deep, firm pressure occasions more or less suffering. Diarrhœa is often, but not always, present. If present, the dejections are more or less frequent, loose, watery, and gelatinous. Tenesmus and the characteristic dejections of dysentery are wanting. I have met with fatal cases in which diarrhœa had not occurred, the inflammation having been limited to the small intestine, as shown by the autopsy. If diarrhœa be a prominent symptom, it probably denotes an extension of the inflammation into the cæcum and colon. Vomiting is apt to be more or less prominent as a symptom. It may be excited sympathetically, or it may denote an extension of the inflammation to the duodenum and stomach. If jaundice occur, it denotes duodenitis. The general symptoms vary considerably in different cases, the variations probably corresponding to the extent, as well as degree, of the inflammation. The febrile temperature is in most cases moderate or slight, and the prostration is not great. The intellect is unaffected, except in severe cases, when delirium may occur, together with tympanites, hiccough, and symptoms denoting adynamia. The duration in favorable cases is brief, convalescence being declared in from a week to ten days.

Pathological Character.—Excluding enteritis occurring in connection with typhoid fever, tuberculosis, and the diseases of infancy, the disease has no special pathological character. It is a simple inflammation of a mucous membrane (intestinal catarrh). It occurs only as a sporadic disease, in this respect differing from dysentery. It differs also from dysentery in not leading to destructive lesions of the affected membrane like those which occur especially in the epidemic form of that disease.

Causation. The susceptibility of the mucous membrane of the small intestine to acute inflammation, after infancy, is slight. It may be produced by dietetic excesses, the use of stimulating food and alcoholic drinks, poisoning with acrid substances, and the use of drastic purgatives. It is sometimes attributable to the action of cold upon the body when heated and perspiring,

local causes being conjoined therewith. Fatigue and debility will co-operate with these causes.

Diagnosis.—Acute enteritis is to be discriminated from dysentery, gastritis, colic, peritonitis and typhoid fever. Assuming that the local symptoms are sufficient to denote inflammation somewhere within the abdomen, the absence of the characteristic dysenteric evacuations, of tenesmus, and of tenderness in the tract of the colon, suffices to exclude dysentery.

Nausea and vomiting, if unusually prominent, may suggest acute gastritis. But the symptoms of acute gastritis point distinctly to the stomach as the seat of disease. This disease may generally be excluded without difficulty. The two diseases, however, may be combined. The inflammation, in some cases, perhaps, extends from the small intestine to the stomach; and, in cases of poisoning with acrid substances, the local effects of the latter may be produced within the small intestine as well as in the stomach.

Colic is a functional affection characterized by intense paroxysmal pain, without tenderness or febrile movement, and is oftener accompanied by constipation than diarrhœa. These points are sufficient for its exclusion.

As regards the local symptoms, acute enteritis approximates to acute peritonitis more closely than to any other affection. But, as a rule, there is a marked disparity in the intensity of the symptoms in these two affections. The pain, tenderness, and tympanites common to both, are, in the great majority of cases, notably greater in peritonitis. Diarrhœa, which is the rule in enteritis, occurs exceptionally in peritonitis. Rigidity of the abdominal muscles, which is one of the diagnostic symptoms of peritonitis, is wanting in enteritis. Moreover, the constitutional disturbance, as denoted by frequency of the pulse, prostration, etc., is much greater in peritonitis. Attention to these points renders the differential diagnosis, in most cases, easy.

The abdominal symptoms in typhoid fever may lead the physician to suppose that disease to be simply enteritis; and, on the other hand, a primary enteritis may be supposed to be typhoid fever. Typhoid fever is to be excluded by the absence of the diagnostic symptoms which attend its development and progress, namely, the characteristic rise of temperature, together with cephalalgia, epistaxis, bronchitis, the rose eruption and delirium. Moreover, the adynamic symptoms in typhoid fever are generally greater than in simple acute enteritis, while the enteric symptoms are less marked.

Prognosis.—Acute enteritis, after infancy, in the majority of cases, is not a disease of great gravity. If it be not associated with any other important affection, and the patient have not a feeble constitution, a favorable prognosis may be generally entertained. The disease, however, sometimes ends fatally. This is to be apprehended when the pulse becomes feeble and frequent, the prostration marked and delirium is developed, the local symptoms persisting. The mode of dying is by asthenia, as in cases of dysentery.

Treatment.—The indications for treatment may be embraced in a few words. An efficient but non-irritating purgative is generally, at first, advisable. Afterward, opium in some form is to be given sufficiently to relieve pain and diarrhœa. It may be administered by either the mouth or rectum, or, alternately, in both modes, or by hypodermic injection. It is to be given in doses proportionate to the urgency of the symptoms, and graduated according to its effects. Fomentations over the abdomen by means of poultices, the water dressing, or spongio-piline, are useful. Moderate stimulation of the surface of the abdomen by sinapisms or liniments is appropriate.

General or local depletion by bloodletting is very rarely, if ever, called for. Mercury, as an alterative remedy, or given to "improve the secretions," is not to be recommended. The supporting treatment is indicated in proportion to the duration of the disease and the tendency to failure of the vital powers. The diet at first should be restricted and bland; but alimentation is, of course, important if supporting measures be indicated. The question of irrigation does not enter into the consideration of the treatment of enteritis, inasmuch as the injected liquid does not readily ascend beyond the ilio-cæcal valve.

Subacute and Chronic Enteritis.

Subacute enteritis is of frequent occurrence, arising either from dietetic errors or an arrest of digestion by exposure to cold, over-exertion, etc. It is not easy to distinguish, practically, cases of transient subacute enteritis from cases of functional diarrhœa; nor is it of much practical consequence to make this discrimination, since the indications for treatment in either case do not materially differ, embracing mild purgation, followed by anodyne remedies and regulation of the ingesta.

Enteritis, acute, subacute, and chronic, is described by some authors under the name *intestinal catarrh*. Here, as in other connections, the term catarrh is not adopted in this work. Authors who treat at length of intestinal catarrh, embrace under this head cases which I shall notice in connection with diarrhœa and intestinal dyspepsia.

Chronic enteritis is usually referable to some prior morbid condition. It very rarely follows acute enteritis. Chronic passive congestion in the portal circulation is a cause of chronic enteritis. It may in this way attend diseases of the liver (as cirrhosis), of the lungs (as emphysema, chronic pleuritis), and of the heart (valvular lesions). All of these affections lead to chronic intestinal inflammation by obstructing the flow of blood through the portal system. The pathological condition is at first chronic passive congestion of the intestines. Bright's disease may be accompanied by chronic enteritis. It is a frequent attendant of tuberculous ulcerations of the intestine, and may occur in chronic tuberculosis without the presence of intestinal ulcers. Chronic enteritis occurs also as a circumscribed inflammation about other forms of intestinal ulcer, about new growths in the intestine, and above strictures of the gut. It is said to be attributable to malaria in some cases. The intestinal mucous membrane in chronic enteritis is coated with mucus and is usually of a slate or ash color from the deposition of pigment. The follicles are often enlarged and pigmented, and may be the seat of ulcers.

The symptoms are the same as those in acute enteritis, but less marked. Constipation may alternate with diarrhœa. In the way of treatment the cause should be, as far as possible, removed. This involves in many cases the treatment of a prior morbid state.

Acute Gastritis.

The term acute has been applied to inflammation of the stomach by different authors with a widely different scope of signification. In the cases of gastritis to which heretofore, by many authors, the term has been restricted, the disease is attended with extreme danger to life, ending fatally, as a rule. In these cases, almost invariably the disease is caused by toxical agents, namely, the corrosive or acrid poisons. Acute gastritis was considered as thus restricted in the previous editions of this work. On the other hand, some authors include under the name acute gastritis, or acute gastric catarrh, gastric inflammation of every grade of intensity, and, also, certain affections

generally regarded as functional. It is in accordance with the application of the term acute to other diseases, to extend its scope as applied to gastritis, so as to embrace all cases in which the inflammation has considerable severity, obliging patients generally to keep the bed. Acute gastritis will be considered in this sense in the present edition of this work. Cases in which the intensity of the inflammation is not sufficient to entitle it to be called an acute disease, will be included under the heading Subacute Gastritis. Cases of chronic gastritis are those in which subacute inflammation is more or less persistent.

Adopting the more comprehensive scope of the term acute gastritis, the disease, exclusive of toxical cases, is not of very frequent occurrence—a fact which would not *à priori* be supposed, considering the quantity of ingesta received into the stomach daily, the various stimulating and irritating substances which often enter into these, the great functional activity of the organ, the amount of blood which it claims during digestion, and the extensive glandular apparatus which it contains.

Anatomical Characters.—More knowledge and caution are requisite in determining the existence of inflammation of the stomach than of any other organ. The stomach often presents after death various appearances simulating disease, but which are independent of any morbid process. These deceptive appearances are dependent chiefly upon two factors, namely, the varying amount of blood in the organ within physiological limits, and the rapid post-mortem softening of the mucous membrane in consequence chiefly of a kind of self-digestion. These changes, which are most intense in the fundus of the stomach, will be mentioned subsequently under the head of softening of the stomach. It is very difficult to discriminate the milder grades of gastric inflammation from post-mortem changes. Hence, the observations of Beaumont upon Alexis St. Martin, who had a fistulous opening into his stomach, are of especial value, and are usually cited as descriptive of the mild forms of acute inflammation of the stomach. These morbid appearances were noticed after indiscretion in eating or following the abuse of ardent spirits, and were accompanied with corresponding local and constitutional symptoms. They rapidly disappeared by proper medication and attention to diet. Beaumont noticed during these attacks of mild gastric inflammation a livid erythematous redness distributed in irregular small patches. Sometimes the mucous membrane was pale. Ecchymoses and oozing of grumous blood from certain red spots of the gastric mucous membrane were also observed. The secretion of gastric juice was deficient, and was replaced by a considerable quantity of ropy, alkaline mucus which became yellowish or muco-purulent when the inflammation was more than commonly severe. Slightly elevated discolored spots, resembling deposits of false membrane, and called aphthous by Beaumont, were also described.

In cases of more severe gastritis, the mucous membrane usually presents irregularly scattered spots of congestion. Occasionally the redness is more diffused, and it may happen that the inner surface of the stomach presents a pale rather than a congested appearance. Ecchymoses, especially upon the summits of the gastric rugæ, may be present in large number. The mucous membrane is thickened, softened, and more opaque than normal. Its surface is coated with a thick layer of tenacious mucus or muco-pus. The swelling may extend to the submucous tissue. The changes are most marked usually in the pyloric portion of the stomach, and are more distinctive of inflammation when in this situation than when in the fundus. Hemorrhagic erosions, which consist of round or oval superficial abrasions of the mucous membrane

upon a hemorrhagic base, are not infrequent.[1] Upon microscopical examination, hyperæmia of the capillaries of the mucous membrane, particularly of those about the summits of the gastric tubules, and extravasations of blood are detected. The intertubular tissue is thickened by the presence of serum and of extravasated red and white corpuscles. The accumulation of white corpuscles or pus-cells is most evident about the muscularis mucosæ. They may also be present in the submucous tissue. The epithelial cells of the gastric tubules may either remain unchanged or may undergo cloudy swelling, that is, become enlarged by the accumulation of albuminous granules (p. 54). In some cases this may be followed by fatty degeneration. Sometimes the tubules appear to be filled with a granular matter containing nuclei, but without distinct cell-boundaries. This parenchymatous degeneration in the glands of the stomach often occurs in fevers, particularly in infectious diseases, and sometimes in phosphorus-poisoning, without evidence of inflammation, but with symptoms of disturbed digestion during life.[2] The cylindrical epithelial cells lining the inner surface of the stomach and the mouths of the gastric tubules become swollen with secretion of mucus which escapes from their free ends. These cells are found in the mucus coating the mucous membrane, but to what extent they desquamate during life is a matter of uncertainty. The solitary follicles of the stomach (or lenticular glands, as they are also called), when present, are often swollen. They sometimes seem to be increased in number in inflammatory conditions of the stomach. Wilson Fox describes the development of follicular ulcers from these structures.

It is impossible to describe here the manifold morbid appearances belonging to toxic gastritis, that is, gastritis produced by swallowing irritant poisons. These are in some cases characteristic of the action of special poisons, and are described in works on special pathological anatomy and on forensic medicine. The corrosive poisons, such as strong mineral acids and alkalies, cause necrosis and sloughing of the mucous membrane to a greater or less extent, and may produce such destruction of the coats of the stomach as to lead to perforation of its wall during life, with the escape of its contents into the peritoneal cavity. Some of these poisons cause the formation of a diphtheritic exudation in the gastric mucous membrane. They may be accompanied by characteristic changes in the color of the mucous membrane and of the contents of the stomach. When corrosive poisons are swallowed, more or less inflammation and perhaps sphacelation may be present in the mouth, pharynx, and œsophagus, but these signs are sometimes wanting. The inflammation, in cases of acute gastritis, may extend into the duodenum.

Clinical History.—Acute gastritis gives rise to pain more or less intense, referred to the epigastrium, together with a painful sense of constriction. The pressure of the diaphragm upon the stomach in inspiration sometimes increases the pain, so that the breathing may be costal, and the number of respirations per minute is increased. Nausea and vomiting are prominent

[1] Brinton describes an especial and severe form of gastritis characterized by the presence of a large number of hemorrhagic erosions. The contents of the stomach are stained with blood. He calls the affection hemorrhagic erosion of the stomach or ulcerative gastritis.

[2] Virchow, in conformity with his views of inflammation, describes this parenchymatous change as inflammatory, and designates the process in this situation as glandular gastritis or gastradenitis; but Cornil and Ranvier justly remark that the inflammatory nature of this lesion is very doubtful. Ebstein finds, in cases of poisoning by phosphorus or by alcohol, the parenchymatous degeneration most marked in the chief or adelomorphous cells of the gastric tubules (Virchow's Archiv, Bd. 55, p. 469, 1872).

symptoms. In some cases the stomach is intolerant of water or the blandest liquids, even in very small quantities. The vomited matter is muco-serous, of a greenish color, the presence of bile being evident from the bitter taste, and not infrequently it is sanguinolent. The acts of vomiting occasion suffering. The thirst is frequently, but not always, intense. The desire for cold water is sometimes so irresistible that the patient is not deterred from drinking it by the painful acts of vomiting which it provokes. Tenderness on pressure over the epigastrium is often marked. The pulse is more or less frequent and small. The temperature of the skin is moderately, and sometimes considerably, raised. The thermometer, however, as a rule, shows but a moderate fever heat, rarely exceeding 101° or 102° Fahr. The bowels are constipated except in cases of poisoning. Dysphagia and aphonia are occasional symptoms. The tongue presents no special morbid appearances. The buccal fluids are diminished, and have an acid reaction. The patient suffers from cephalalgia. The mind is depressed, and the expression is anxious and haggard. If life be not speedily destroyed, and the disease run on to a fatal termination, vomiting of black, grumous, coffee-ground matter may occur, especially in cases of toxical gastritis. Towards the close of life the contents of the stomach are ejected by acts of regurgitation rather than by vomiting. The prostration in fatal cases becomes extreme. Hiccough occurs. The pulse becomes very frequent and thready. Coldness of the surface is marked. The mode of dying is by asthenia. If the disease end in recovery, improvement in all the symptoms takes place slowly; convalescence is gradual, and the inflammation may persist in a chronic form. In cases of gastritis produced by the corrosive poisons, if perforation of the stomach occur, the symptoms of peritonitis are added. Jaundice occurs in some cases, showing that the inflammation extends into the duodenum. The foregoing sketch of the symptomatology applies to cases of marked severity. In less severe cases the symptoms are essentially the same, with a lesser grade of intensity.

Pathological Character.—The stomach, aside from its office as a receptacle of the ingesta, is a glandular organ, furnishing daily a large quantity of an important secretion—the gastric juice. In its reluctance, so to speak, to take on acute inflammation from the internal and inappreciable causes which give rise to the so-called spontaneous inflammations in other situations, it resembles other glands, such as the liver, pancreas, kidneys. When acute inflammation is spontaneously developed in this situation, it does not differ in pathological character from acute inflammation seated elsewhere in a mucous structure. The gravity of the disease depends on the physiological relations of the stomach. Acute gastritis produced, traumatically, by the action of caustic or irritant poisons, is developed like inflammation from the action of the same local causes in other situations.

Causation.—Exclusive of the acrid or corrosive poisons, the most frequent cause, in this country, is spirit-drinking. I have known the disease to follow directly a debauch, and prove rapidly fatal. A person with chronic gastritis induced and kept up by habitual spirit-drinking, is liable to the acute affection after an unusually excessive indulgence. Exposure to cold may act as an auxiliary cause. In a case under my observation, the patient being an habitual drinker, the disease followed sleeping in a cold cellar. Over-repletion of the stomach with stimulating and indigestible food, may sometimes give rise to acute gastritis. This so-called crapulous gastritis is generally subacute. It is a traditional error to enumerate as causes drinking cold water when the body is perspiring, intense mental emotions, and contusion of the abdomen.

Diagnosis.—The symptoms of acute gastritis are strongly diagnostic. There is greater probability of the disease being incorrectly supposed to exist, than of its being mistaken, when existing, for other diseases. Vomiting, however frequent and persisting, is never alone sufficient evidence of gastritis. I have known a case of chronic meningitis with persistent vomiting to be treated for acute gastritis, and the error not discovered prior to the autopsy. Peritonitis, if accompanied with vomiting, may assume an appearance of gastritis, but the diffusion of tenderness over the abdomen, the tympanitic distension, and the rigidity of the abdominal muscles, generally suffice for this differential diagnosis. Gastritis has been mistaken for pneumonitis, but physical exploration of the chest should enable the physician to detect or exclude the latter affection. The danger of overlooking gastritis developed after a debauch, was dwelt upon by Stokes.

Gastralgia was formerly confounded with gastritis. The paroxysmal recurrence of pain, or its occurrence in marked exacerbations, the absence of febrile movement, of vomiting, as a rule, and of tenderness on pressure, and the ability to take food sometimes with relief of the pain, sufficiently characterize the former affection as neuralgic.

With a view to appropriate antidotal treatment, and, also, in a medico-legal point of view in certain cases, it is desirable to determine from the symptoms whether acute gastritis be attributable to poison. This is always to be suspected in severe cases, if other causes be not evident. Burning in the throat is complained of, if a caustic or corrosive poison have been taken, and the local action of the poison may be seen in the mouth and fauces. The matters vomited are apt to contain blood. Diarrhœa is more apt to occur. If caused by a poison, the disease is developed suddenly, and inquiry is to be made to ascertain if the sudden development were not immediately preceded by a meal or the ingestion of something in the way of food or drink.

Prognosis.—Cases of acute gastritis, in the restricted sense in which the term acute was formerly used, were, in the great majority of cases, fatal. In the more comprehensive scope of the term, the disease ends in recovery, as a rule, if toxical cases be excluded. Death sometimes takes place within a few hours, patients falling quickly into a condition of collapse. These cases, however, are exceptional. The mode of dying is generally by slow asthenia.

When the disease is due to the action of a corrosive poison, the danger will depend, other things being equal, on the amount of local injury.

Treatment.—The indications for bloodletting are not present in this disease. Bearing in mind that the danger is from asthenia, and that life is sometimes quickly destroyed, the abstraction of blood is not admissible. The first and most important object in the treatment is to secure for the inflamed organ absolute rest. With reference to this object, the less of anything introduced into the organ the better. To allay intense thirst, small pieces of ice may be swallowed, or iced water taken often, in a very small quantity at a time. The physician should resist the temptation to try in succession the host of remedies to allay vomiting, all of which will be likely to aggravate this distressing symptom. It is desirable to administer opiates in order to quiet the stomach and render the system more tolerant of the disease. A salt of morphia placed dry upon the tongue may be tried, and, if vomiting be provoked by this mode of administration; it should be administered hypodermically, or some form of opiate given per enema. Fomentations or a small blister may be applied over the epigastrium. Cathartics are inadmissible. The bowels may be moved by stimulating enemas. Mercury, either in large or small doses, is not indicated. The importunities of the

patient for an emetic are to be resisted. There may be a feeling as if the stomach were distended, or as if there was an accumulation aggravating the distress. This feeling arises from the inflamed state of the membrane, as tenesmus is incident to inflammation of the rectum.

Alimentation is not less important than in other diseases, and, in proportion as the symptoms denote danger in the direction of asthenia, supporting measures of treatment are indicated. The stomach will not tolerate alcoholics and food; moreover, their introduction into the stomach conflicts with the most important object of treatment, namely, absolute rest of the inflamed organ. The rectum is to be substituted for the stomach as regards the reception of ingesta. This is a disease in which rectal alimentation is of invaluable service. Alimentary support may be adequately provided thereby during a period as long as may be required, that is, until the acute symptoms have subsided, and the stomach will tolerate bland nourishment. From three to four ounces of either defibrinated blood, Leube's pancreatic meat emulsion, or his "meat solution," or milk with the addition of egg (the election of any of these articles being made after experimental trials, and perhaps the different articles employed in alternation), may be injected every four or six hours. If alcoholic support be indicated, spirit may be added to the rectal food, according to the urgency of the indication, or the latter may be administered hypodermically. The addition of a little laudanum to each injection is generally advisable. Thirst may be relieved by the injection of water from time to time, and frequent sponging of the body. The danger from the disease is much lessened and the duration shortened by pursuing this course.[1]

Milk, with the addition of lime-water, will be likely at first to be best borne by the stomach, given in small quantities at short intervals. Other forms of food are to be gradually added. After the inflammation has ceased, the stomach is left in an atonic condition, and remedies of a tonic character are indicated during convalescence. If the acute end in the chronic form of inflammation, the treatment due to chronic gastritis is to be employed.

Acute gastritis caused by the acrid or corrosive poisons is to be treated after the plan just stated, with the addition of measures having reference to the evacuation and neutralization of the poisonous substance. Emetics are to be promptly given, and, if they fail to act efficiently, the stomach-pump is to be resorted to, provided the poison be one which can be ejected. Arsenic, corrosive sublimate, alcohol, antimony, cantharides, copper, phosphorus, together with a great number of vegetable irritants, such as capsicum, gamboge, croton oil, etc., may be expelled from the stomach; but, if any of the corrosive acids have been taken, reliance must be placed on the prompt administration of antidotes. Antidotes are also to be given after the employment of emetics or the stomach-pump to effect the removal of acrid poisons. For details respecting the management of cases of poisoning, the reader is referred to works which treat of toxicology.[2] I shall simply subjoin, for the

[1] The pancreatic meat emulsion is prepared as follows: To five ounces of finely scraped meat, add one and a half ounce of finely chopped pancreas, and three ounces of warm water. The mixture should have the consistence of thick soup. Leube's meat solution is prepared by adding hydrochloric acid with water, and employing heat by means of a Pepin's digester (*vide* "Ueber die Therapie der Magenkrankheiten, von W. O. Leube." Sammlung klinischer Vorträge, von Volkmann, No. 62, Leipzig, 1873). The bowels should be thoroughly washed out by a large enema before commencing rectal alimentation, and afterward from time to time. Laudanum added to the injections promotes their retention, and, probably, their absorption. Unsalted beef essence is to be included among the articles of rectal diet.

[2] Taylor on Poisons may be consulted for this purpose; also, article *Poisons* in Dunglison's Medical Dictionary.

convenience of the practitioner, an enumeration of the antidotes for the more important of the poisons which act locally upon the stomach.

Arsenical Preparations: The hydrated sesquioxide of iron is the special antidote. It should be recently prepared, and given in large quantity. If this preparation be not immediately available, the sesquioxide or common red oxide of iron (crocus martis) may be given in its stead. Bouchardat advises to combine with the preparation of iron, magnesia, in order to promote the passage of the iron from the stomach into the intestines.

Corrosive Sublimate and other Salts of Mercury: The most reliable antidote is albumen, and the white of eggs is the best and most available article.

Salts of Copper: Albumen is an antidote. Iron reduced by hydrogen and the hydrated persulphate of iron are said by Bouchardat to be antidotal both to the salts of mercury and copper.

Tartar Emetic: Substances containing tannin in abundance, and magnesia.

Nitrate of Silver: Chloride of sodium.

Mineral Acids: Magnesia or chalk mixed with water or milk; the alkaline carbonates or soap.

Oxalic Acid: Magnesia, chalk; whiting or plaster scraped from the wall of an apartment may be given, mixed with water. Alkalies are not to be given.

Ammonia: Vinegar or any of the vegetable acids.

Potassa and Soda: The same.

Subacute Gastritis.

Subacute gastritis, not becoming chronic, but of transient duration, occurs not infrequently. It is not easy to say with positiveness how frequently it occurs, because practically it is difficult to draw the line of demarcation between slight inflammation and merely functional disturbance in this situation. Subacute gastritis doubtless enters into certain cases of the affection which will be noticed in connection with functional disorder of the stomach, under the name acute dyspepsia. Subacute inflammation of the stomach is much more frequent in infants and young children than in the after periods of life. As here considered, reference will be had chiefly to the affection occurring subsequent to the period of infancy.

The degree of inflammation in different cases of subacute gastritis varies, being either slight, moderate, or considerable, as evidenced by the local and general symptoms. The local and general symptoms are marked according to the intensity of the inflammation. In cases in which the inflammation is slight or moderate, the appetite is impaired but not lost. The ingestion of food is followed by uneasiness or distress referred to the epigastrium, and by symptoms denoting indigestion, namely, flatulency, eructations, etc. Thirst is a symptom usually more or less prominent. Tenderness over the epigastrium and a furred or coated tongue are other symptoms. The urine is high-colored and loaded with the urates. In some cases there is constipation, and in other cases diarrhœa, the latter being due to intestinal indigestion. Pain in the head is a frequent, and sometimes a prominent, symptom; and when connected, as it frequently is, with nausea, it is one of the forms of "sick headache." There may be slight pyrexia, but it is frequently or generally wanting, except after the ingestion of food or stimulants. When transient febrile movement is not thus produced, the pulse is usually feeble, and the extremities are apt to be cold. There is more or less general debility, but the sense of weakness exceeds the actual reduction of strength. The spirits

are depressed, and the suffering may be considerable from malaise without any definite location of pain or distress.

This is a sketch of a class of cases which the practitioner meets with frequently, and which, together with cases of the affection to be considered in another chapter under the name acute dyspepsia, is popularly known as a "bilious attack."

If the gastric inflammation be greater, approximating in intensity to acute gastritis, the local and general symptoms are more marked. There is suffering from gastric distress, and sometimes from a dull, obtuse pain in the region of the stomach. The epigastric tenderness is often considerable, anorexia is complete, with loathing of food and nausea. Vomiting is apt to be a prominent symptom. Mucus is vomited in abundance; and, if the efforts of vomiting be prolonged, bile is rejected. The patient experiences a temporary sense of relief after vomiting. The feeling is as if the stomach were distended, and acts of vomiting are provoked and aided by voluntary efforts with the idea that if the contents of the stomach were effectually discharged the relief would be permanent. This feeling arises from the inflamed condition of the membrane, and is analogous to the sensation connected with tenesmus in dysentery. It may be called gastric tenesmus. Thirst is apt to be urgent, and cold drinks are craved. The tongue is coated at first, but, in the course of the affection, it may become clean and reddened. Either constipation or diarrhœa may exist. There is more or less febrile movement, with evening exacerbations, as shown by the pulse and axillary temperature; the latter, however, rarely exceeds 100° Fahr. Chilly sensations and rigors are common, continuing for a few seconds and recurring irregularly. Cephalalgia is generally marked, and in some cases is accompanied by a sense of tension, or a feeling as if the head would break. There is often a sense of prostration, with depression of spirits and sometimes a notable degree of mental apathy. In cases of maximum severity, subacute gastritis so closely approximates to acute gastritis that there is scarcely a well-marked line of division between the two forms of the disease.

In cases of gastritis with considerable pyrexia, the disease is sometimes called "gastric fever." This name implies that the disease is primarily or essentially a fever, whereas the fever is purely symptomatic and secondary to the gastric inflammation.

Subacute gastritis, if the inflammation be slight or moderate, is usually of short duration, convalescence taking place in a few days. If the inflammation have considerable intensity, the duration of the disease is from a week to three weeks. If the inflammation persist much beyond the latter date, it is to be considered as chronic.

Subacute gastritis, in some cases, is evidently of dietetic origin. It is sometimes attributable to the decomposition of ingested aliment, owing to a deficiency of gastric juice, or to the quantity of food ingested being out of proportion to the digestive capability of the stomach, and to the ingestion of food difficult of digestion, or in which putrefaction had begun prior to the ingestion of it. Persons who are habitually addicted to over-indulgence in eating, or to highly seasoned dishes and the free use of condiments, are doubtless more liable to this affection than others, as a consequence of a gluttonous meal, or when, from any cause, stomach digestion is arrested. The affection sometimes follows a prolonged debauch. The habitual free use of spirits begets a liability to it. It occurs especially among drunkards. It may be caused by any of the acrid or irritant poisons not taken in sufficient quantity to produce acute gastritis. The so-called uræmic gastritis is caused by the irritant effects of the carbonate of ammonia formed by the decomposition of urea upon the gastric mucous membrane; and it is not improbable, as some

authors have maintained (Garrod, Charcot), that in some cases of gout, uric acid is eliminated by the stomach, and by a similar irritant effect causes gastritis. In a certain proportion of cases the causes, both remote and proximate, are not apparent.

An affection to which subacute gastritis is closely affiliated, is that to be considered under the name acute dyspepsia. Gastric inflammation doubtless enters into certain cases of the latter affection, but the functional disturbance is disproportionately great as compared with the amount of inflammation, and is not to be accounted for by the latter; hence, the propriety of considering it a functional affection of the stomach. The differential diagnosis of these affections is not, practically, of great importance. The symptoms of gastritis are present in certain cases of remittent fever, and, perhaps, they proceed actually from subacute inflammation of the stomach in these cases. The symptomatic phenomena of remittent fever, however, are sufficiently distinctive to render its discrimination from simple gastritis easy. Cases of ephemeral fever, or febricula, are to be discriminated by the want of proportion between the febrile phenomena and the gastric symptoms. Cases of continued fever, typhus and typhoid, very rarely present symptoms of gastritis with sufficient prominence for the differential diagnosis to be a matter of question. In general, the diagnosis of subacute gastritis is not difficult.

In the treatment of subacute gastritis, rest of the inflamed organ is of primary importance. If the inflammation be but slight or moderate, it will suffice to place the patient on a diet reduced in quantity, consisting of milk with lime-water, and farinaceous articles. In cases of greater severity, complete abstinence for two, three, or four days may be advisable; the vomiting and loathing for food will be likely to secure this end without any injunctions on the part of the physician. In the mean time, if the symptoms denote exhaustion, the patient may be supported by rectal alimentation. The abstraction of blood, either locally or by venesection, is never indicated. Benefit may be derived from sinapisms or a blister over the epigastrium. Emetics and purgatives are contra-indicated. The sensations of the patient may lead to a desire for both, especially the former, but they do not effect any desirable object, and their local action upon the inflamed member will do harm. If the bowels be constipated, simple enemas may be employed. Mercury is not indicated more than in cases of inflammation affecting the mucous membrane or other portions of the digestive system. On the other hand, remedies to soothe the inflamed membrane, and to allay vomiting, are indicated, namely, bismuth, hydrocyanic acid, hyoscyamus, and especially the salts of morphia. Small pieces of ice may be swallowed, or iced water given in a small quantity at a time and often repeated, if found to be grateful to the patient. Carbonated water is not only taken with comfort, but appears to be useful.

It is important not to continue the abstinence from food or a great reduction of diet too long. As soon as nutritious articles of food are well tolerated by the stomach, they are admissible. The improvement of diet should be made gradually and tentatively. During convalescence the mineral acids are useful as tonics; and, after the inflammation has ceased, other tonics may be appropriate. Patients who are spirit-drinkers should be told of the connection of the disease with their habits.

Chronic Gastritis.

Chronic gastritis is not infrequent, although it is not as common an affection as was supposed some years ago. Chronic functional disorders were formerly considered as inflammatory. It is not always easy to discriminate

clinically between chronic inflammation and the functional affections embraced under the name dyspepsia. The differential points involved in this discrimination will suffice for the clinical history and diagnosis of the affection. The affection occurs oftener in middle and advanced life than in children and young persons. It occurs in men oftener than in women.

Anatomical Appearances.—The changes in chronic gastritis are most frequently present and most marked in the pyloric region of the stomach. This localization applies also to the majority of morbid processes in the stomach. The color of the mucous membrane varies in different cases. It may be red, brown, ash-gray, slate-colored, whitish. A bluish-red color, either diffusely or in spots, is usually present in chronic inflammation attendant upon prolonged passive congestion of the stomach, such as accompanies cirrhosis of the liver, emphysema of the lungs, and heart-disease. Ecchymoses and hemorrhagic erosions are frequently present. The mucous membrane, as a rule, is more or less pigmented, and this gives rise to brown, ashy, and slate colors. The pigment generally appears as little dots scattered over the mucous membrane. The same pigmentation often co-exists in the intestinal tract. It is most frequent where there is mechanical congestion of the stomach in consequence of portal obstruction. It is referred to alterations in the hæmoglobin of extravasated red blood-corpuscles (Part I. p. 59), and is therefore regarded as a sign of preceding congestion and hemorrhage. The pigment exists in the form of dark granules, either free or in cells, in the intertubular tissue, and sometimes in cells within the tubules. The inner surface of the stomach is coated with a thick layer of viscid mucus or muco-pus. The consistence of the mucous membrane is sometimes peculiarly firm and tough; at other times it is more or less softened. The thickness of the mucous membrane varies in different cases and in different parts of the stomach in the same case. Chronic inflammation leads both to thickening and thinning of the mucous membrane. The latter result is often, although not invariably, consecutive to the former. The mucous membrane is usually thickened, but not infrequently it is atrophied in certain places, and, exceptionally, the whole membrane may be abnormally thin. Both in healthy and diseased stomachs the mucous membrane of the pyloric region not infrequently presents little rounded elevations, separated by slight furrows. This condition, compared sometimes to granulations upon wounds, is called mamillation or *état mamelonné* of Louis. When present in healthy, and often in diseased, stomachs, it is due to contraction of the muscularis mucosæ (Brücke's muscle). In chronic gastritis, however, it may also be referable to irregular thickening of the mucous membrane. The furrows may correspond to atrophic spots. Exceptionally polypoid growths, due to localized increase of connective tissue and enlargement and proliferation of the gastric tubules, are present, even in considerable number (gastritis polyposa). Little cysts, about a millimetre in diameter, are frequently observed in the mucous membrane. They are the result of distension of parts of the gastric tubules with a clear mucoid secretion. Sometimes the cysts attain a much larger size. The submucous tissue is frequently thicker and denser than normal. There may also be some hypertrophy of the muscular coat. Upon microscopical examination the interstitial tissue of the mucous membrane is usually found to be increased in amount. The gastric tubules may be enlarged in consequence of swelling and parenchymatous or fatty degeneration of their epithelial cells. Usually the tubules are affected in groups, some remaining unchanged. The degenerative change may lead to complete destruction of the epithelial cells. The tubes are then partly or completely filled with albuminous and fatty detritus. Finally, the tubules may become atrophied, and in some places even obliter-

ated. According to W. Fox, fatty degeneration may occur in the connective tissue as well as in the glands. The cystic transformation, to which reference has been made, is attributable to partial occlusion of the tubules in consequence of the new growth of interstitial tissue. A change which occasionally occurs is proliferation or adenomatous growth of the tubules. In the neighborhood of the pylorus little villous projections of vascularized connective tissue are often met with in chronic gastritis. In the atrophied portions of mucous membrane the tubules are shorter and narrower than normal. Such places have usually a smooth surface and are pigmented.

Symptoms denoting indigestion or difficult digestion are present in cases of chronic gastritis, but these, alone, are not diagnostic, since they alike exist in cases of dyspepsia. Pain may not be present, and, if present, is not distinctive. A burning sensation or a feeling of heat in the gastric region is somewhat diagnostic. Tenderness over the epigastrium is somewhat diagnostic, provided it be limited to that region and constant, that is, not present merely during the process of digestion or when the stomach is distended. Thirst is diagnostic, if habitual, that is, present not only during the process of digestion, but at other times. The appetite is much oftener impaired in connection with chronic gastritis than in cases of dyspepsia; the appetite is generally preserved, and often craving, in the latter. The nutrition is oftener defective in cases of chronic gastritis; dyspeptics often preserve their weight unimpaired. In chronic gastritis, stimulating articles of food, such as meat and condiments, are not as well borne as bland aliments, the reverse being oftener the case in dyspepsia. Alcoholic and other stimulants produce gastric distress in cases of chronic gastritis, whereas, they often relieve distress incident to merely functional disorder. Nausea and vomiting are more apt to occur in connection with chronic gastritis, excluding cases of so-called acute dyspepsia and certain cases of functional disorder characterized by vomiting; in ordinary cases of dyspepsia, nausea and vomiting are not common. A slight grade of febrile movement is sometimes observed in chronic gastritis, and very rarely in a purely functional disorder.

The diagnosis is to be based on the combination of more or less of the foregoing differential points. In making the diagnosis, certain structural affections of the stomach are to be excluded, namely, carcinoma and ulcer. The diagnostic symptoms of these affections will be considered in the next chapter.

Chronic gastritis may follow an acute or subacute inflammation of the stomach developed spontaneously or produced by the acrid or corrosive poisons. It may proceed from excesses in eating or spirit-drinking, and, on the other hand, it is stated that long fasting or too rigid dieting may give rise to it. In dogs destroyed by starvation, Andral found the stomach inflamed and ulcerated; but similar experiments made by Martigny were negative as regards appearances of inflammation in this organ.[1] Stark, who fell a victim to experiments in dietetics in 1869, had symptoms of gastritis developed during prolonged abstinence. Arsenic introduced into the system by absorption from an external wound, gives rise to gastritis, as ascertained by Brodie and verified by the observations of others. Chronic gastritis also frequently results from long-continued venous congestion of the stomach, in consequence of obstacles to the circulation in the liver, lungs and heart. This chronic congestion is most intense, *cæteris paribus*, when the obstacle is in the liver. Emphysema of the lungs, chronic pleurisy, valvular lesions of the heart, and especially cirrhosis of the liver, are often accompanied by chronic gastritis. It occurs also in connection with gout, and with pulmonary phthisis. Chronic

[1] Magendie, Journal de Physiologie, tome viii.

gastritis occurs in certain cases of renal disease involving uræmia; the explanation is that already given, namely, the carbonate of ammonia which is formed from the decomposition of the urea eliminated by the gastric mucous membrane, acts as a local irritant.

The first point in the treatment is the removal of dietetic causes which may have originated or which tend to perpetuate the affection. The patient is to be placed on a bland and easily-digested diet, consisting of milk, eggs, stale bread, soft-boiled rice, and other farinaceous articles—articles digested in the small intestine. Meat and stimulants are to be interdicted. For a short time it may be advisable to reduce the quantity of food below the amount which the wants of the system require. Food should be taken in small quantities and at shorter intervals than in health. Moderate counter-irritation over the epigastrium is useful. The remedies to be administered are few. Solicitations for emetics and cathartics are to be resisted. Patients are apt to declare that they are "bilious," or that there exists "foulness of the stomach," and, hence, that they need evacuant medicines. But in place of medicines which, from their irritant action, will tend to increase or prolong the inflammation, remedies to soothe the inflamed membrane are indicated, namely, small doses of morphia, hyoscyamus, hydrocyanic acid, bismuth, etc. After the inflammation has ceased, functional debility or atony remains. Tonics and improved diet are then required. It is a point of delicacy to determine when to make this change in the treatment. It is like resorting to passive motion in cases of fracture or dislocation. The change is to be commenced tentatively, and continued, or not, according to the effect. The symptoms of functional disturbance and the indications for treatment, which may be present after the inflammation ceases, will be considered in connection with dypepsia (*vide* Chapt. V.).

Phlegmonous Gastritis.

By phlegmonous gastritis is understood suppurative inflammation of the walls of the stomach. This disease is very rare. The submucous tissue is primarily involved, but the inflammation may extend to the other coats of the stomach. Synonyms for this disease are gastritis submucosa (Dittrich), suppurative linitis (Brinton), and interstitial suppurative gastritis (Auvray). The affection appears either as a circumscribed collection of pus in the walls of the stomach, or as a diffuse purulent infiltration of the ventricular coats. The former condition, which is the more frequent, is also called abscess of the stomach, which may be single or multiple. It may attain the size of the fist. The purulent collection is in the submucous coat and frequently invades the muscular layer. The mucous and serous layers may be intact. There is usually, however, a localized peritonitis over the seat of the abscess. The abscess may rupture through the mucous membrane into the cavity of the stomach, or, less frequently, through the serous coat into the peritoneal cavity. In rare instances recovery may take place after the escape of the pus into the cavity of the stomach. A cicatrix then results, and this may lead to stenosis of the stomach.

Purulent infiltration of the submucous coat usually involves only a part of the stomach; it may, however, affect its whole extent. The suppurative process may also extend into the lower part of the œsophagus and into the duodenum. The wall of the affected portion of the stomach is thickened; it may be six or eight times its normal dimensions. The mucous membrane is usually swollen and spongy in texture. It generally presents a number of little round openings, through which pus can be pressed out. Sometimes larger irregular ulcers are present. Upon cutting through the wall of the

stomach, the accumulation of pus is found to be greatest in the submucous coat, whence purulent septa often extend between the bundles of the muscular coat. The subserous tissue, also, frequently contains pus. In fact, while the lax submucous and subserous tissues suffer the most, microscopical examination usually shows the presence of large numbers of pus-cells in the firmer mucous and muscular coats of the stomach. Purulent infiltration may be accompanied by the presence of circumscribed abscesses. The suppurative inflammation, exceptionally, may not have advanced to the breaking down of tissue, so that the infiltration with pus-corpuscles is only evident upon microscopical examination. Circumscribed inflammation of the serous covering of the stomach (perigastritis) is often present, and not infrequently general peritonitis. Infectious thrombi may form in the veins of the stomach, and, by the separation of emboli, lead to secondary abscesses in the liver and lungs. Phlegmonous gastritis is one of the causes of suppurative pylephlebitis. In a number of cases there have been evidences of a previous chronic gastritis, with fibrous thickening of the submucosa.

Etiologically, phlegmonous gastritis may be divided into two varieties—a primary, idiopathic, and a secondary, metastatic. Metastatic phlegmonous gastritis, which is usually in the form of circumscribed abscess, is secondary to severe infectious diseases, such as pyæmia and puerperal fever. The primary variety has been observed most frequently in drunkards. Other causes which have been assigned, the efficiency of which is doubtful, are injuries in the region of the stomach, errors in diet, and ulcer of the stomach. In most cases of the primary variety it is impossible to assign an efficient cause. Males are more frequently attacked than females. It has usually occurred in the middle period of life.

The symptoms of the metastatic variety are usually obscured by those of the primary disease. The idiopathic form generally runs an acute course, terminating in from one to three weeks. Its progress, however, may be chronic and insidious. As a rule, the disease begins with a chill, and may be attended by repeated chills. The temperature is elevated, often considerably. The pulse is rapid and feeble. The patient suffers from thirst and anorexia. There are usually severe pain and tenderness in the epigastric region, but these may be absent. Vomiting and retching are prominent symptoms. The stomach is generally more or less distended with gas. In some cases there has been constipation and in others diarrhœa. Prostration early sets in. Brinton observed icterus in some cases. Toward the end the patient becomes delirious. Death is usually preceded by a state of collapse. The fatal termination is sometimes sudden. These symptoms may be complicated by those of acute peritonitis. As a rule, no pus has been detected with the naked eye in the vomited material. Sometimes, however, when an abscess has burst into the stomach, a large quantity of pus has been vomited. Occasionally an abscess in the wall of the stomach is of sufficient size to be felt during life as a tumor. The duration of the disease is usually from two to ten days, but may be longer.

There are no diagnostic symptoms of phlegmonous gastritis. Its recognition during life is usually impossible. It may, however, sometimes be suspected by excluding other conditions, especially general peritonitis. In some cases its presence has been rendered probable by the detection of a swelling, connected with the stomach, the disappearance of which was followed by the vomiting of a quantity of pus. But even in this case it would often be difficult to exclude the rupture of an abscess which had taken its origin outside of the stomach; for instance, a circumscribed collection of pus in the peritoneal cavity.

The termination of phlegmonous gastritis is usually fatal. There is reason, however, to believe that abscess of the stomach may end in recovery.

The treatment indicated in phlegmonous gastritis has for its objects complete rest of the affected organ and the relief of pain. The first of these objects is secured by rectal alimentation and opiates. The relief of pain is effected by the latter, in conjunction with emollient and soothing applications over the epigastrium.

Croupous and diphtheritic inflammations of the stomach have been described, but they are little understood and are without clinical interest, being unattended by distinctive symptoms. Pseudo-membranous gastritis is usually secondary to some other disease, such as croup and diphtheria, typhoid fever, pyæmia, puerperal fever. It may be produced by swallowing acrid poisons.

Chronic Interstitial Gastritis. Cirrhosis of the Stomach. Hypertrophic Stenosis of the Pylorus.

This disease is characterized by thickening of the walls of the stomach in consequence of new growth of connective tissue. The affection was clearly described by Brinton, who proposed for it the names plastic linitis and cirrhosis of the stomach. It has also been called fibroid degeneration or infiltration, induration, sclerosis, and hypertrophy of the stomach. The name chronic interstitial gastritis implies that the morbid process is a chronic inflammation of the interstitial tissue of the stomach, analogous to that of the liver in cirrhosis. The affection is referred to by most German writers under the name chronic catarrhal gastritis, with which, although often associated, it should not be confounded. The disease, although rare, has been observed in several typical cases. In such cases the stomach is small and increased in weight and density. The diminution in its capacity may be extreme. Its cavity may not be larger than a medium-sized pear. In certain instances the stomach has been described as normal in size or even dilated. The thickness and increased density of the ventricular walls may be such that, upon incision, the organ does not collapse. The stomach-wall may measure an inch or more in thickness. The organ may be uniformly affected, or the change may be greatest in the pyloric region. When the pyloric region is alone affected, the remainder of the stomach is dilated instead of contracted. Upon examining a section through the wall of the stomach, the coats are found to present an unnatural uniformity. Their consistence is firm, almost cartilaginous. The new growth of connective tissue, to which the change is mainly due, involves usually all of the coats of the stomach, but more especially the submucous, which appears as a dense, white layer. The muscularis, especially the transverse layer, is frequently much hypertrophied, and presents a grayish, translucent appearance. It is usually invaded by the new growth of fibrous tissue. The subserous tissue is also thickened and fibrous. The serous coat is of a peculiar opaque, pearly-white color. The mucous membrane may be intact, but is generally involved in the morbid change. Its interstitial tissue is thickened, the tubules are atrophied and may even disappear over a considerable extent of the stomach.[1] In some cases no changes in the gastric glands have been noticed.

The thickening is sometimes confined to the neighborhood of the pylorus. This condition has been called fibroid degeneration of the pylorus (Habershon)

[1] In a case reported by Nothnagel and examined microscopically by W. Müller, glands were found only in the pyloric region. Deutsches Archiv f. klin. Med., Bd. 24, p. 353, 1879.

and hypertrophic stenosis of the pylorus (Lebert). In works devoted especially to diseases of the stomach, it appropriately receives separate consideration. The thickening here also is due to formation of new fibrous tissue and to hypertrophy of the muscular coat. This lesion induces stricture of the pylorus, which may amount almost to complete closure of the orifice. In consequence of pyloric obstruction, the stomach becomes dilated, and its muscular coat hypertrophied. In a case of hypertrophic stenosis of the pylorus, related by Nauwerk,[1] the stomach occupied two-thirds of the abdominal cavity. This lesion has been confounded with scirrhous cancer of the pylorus, from which it is to be distinguished only by microscopical examination. In some cases of hard cancer of the stomach, the cancerous alveoli are few in number and separated by a large quantity of fibrous tissue.

The symptoms of cirrhotic contraction of the stomach are not sufficiently distinctive to admit of a positive diagnosis. The affection is a grave one, and usually terminates fatally. Sometimes, like other severe affections of the stomach, it is unattended by symptoms. Usually the symptoms at first are those of simple chronic gastritis, such as indigestion, loss of appetite, vomiting, feeling of oppression in the epigastrium; but these symptoms are inconstant and possess nothing characteristic. As the disease progresses, a more severe affection is suspected, usually cancer of the stomach. The patient loses flesh and strength. In an interesting case reported by Nothnagel, the patient presented all of the essential symptoms of pernicious anæmia, including hemorrhages in the retina and elsewhere. To a certain degree characteristic of cirrhotic contraction are the inability to take more than a small quantity of food or drink at a time, and the sense of fulness which follows the ingestion of this small quantity. The patient thus suffers from inanition, both in consequence of the small capacity of the stomach, and from the disturbance with its digestive functions. Sometimes, but not always, a hard mass presenting the contracted contours of the stomach can be felt through the abdominal wall. In a few cases the vomiting of coffee-ground material has been noted, but this occurrence is exceptional. Pain is not usually a prominent symptom. Constipation has been the rule.

In a case under my observation, in which the walls of the stomach were found to be from half an inch to an inch in thickness everywhere except at the pyloric third, the patient, up to a few weeks before death, supposed that he was simply dyspeptic, his ailments not leading him to seek medical advice. In this case the organ formed a resisting, movable tumor, felt through the abdominal walls, and the disease was supposed to be carcinoma.

When the fibroid metamorphosis is confined to the pylorus, the symptoms are those of stenosis of the pyloric orifice, combined with dilatation of the stomach. Prominent among these symptoms are vomiting of accumulated ingesta and obstinate constipation. The symptoms are explicable by the obstacle to the entrance of substances from the stomach into the intestine. The symptoms and signs of dilatation of the stomach will be considered hereafter. Nauwerk, in the report of the case of hypertrophic stenosis, to which reference has been made, gives an interesting example of the length of time during which ingesta may remain in the stomach. He found at the autopsy, in the stomach, cherry-stones which had been swallowed three months previously, and which had remained, although the stomach had been washed out and the patient had vomited repeatedly. Sometimes the thickened pyloric part of the stomach can be felt during life as a small, hard, movable tumor.

The diagnosis of cirrhotic contraction of the stomach and of hypertrophic stenosis of the pyloric valve, cannot usually be made with any degree of cer-

[1] Nauwerk, Deutsches Archiv f. klin. Med., Bd. 21, p. 578, 1878.

tainty. The disease is most apt to be confounded with cancer of the stomach. The following points are to be considered in attempting to reach a probable diagnosis: cirrhosis of the stomach is often of much longer duration than cancer; it may attack persons much younger than those usually affected with cancer; pain in the region of the stomach and vomiting of blood are less frequent and prominent symptoms in cirrhosis than in cancer; the inability to take more than a small quantity into the stomach is a more marked symptom in cirrhosis than in cancer. But upon no single one of these points can much positive value be placed in a differential diagnosis. Nor is too much weight to be placed upon the detection of a hard tumor simulating the contours of the stomach. Such an occurrence is rare and would not suffice to exclude cancer. It has been proposed to determine the size of the stomach by causing the evolution of carbonic acid gas in its cavity, according to the method first proposed by Frerichs (*vide* Dilatation of the Stomach, Chapter III.), but this procedure has not yet been employed in contraction of the stomach, and could not well serve as a basis of a positive diagnosis. The diagnosis of cirrhosis of the stomach, then, may in certain cases be rendered probable by a combination of favorable circumstances, but can hardly become a certainty.

The etiology of chronic interstitial gastritis is obscure. Most writers concur in regarding spirit-drinking as one of the causes. It is most frequent in men and after forty years of age. It has, however, been met with in temperate persons of either sex and in early life. It is often preceded and accompanied by the symptoms of chronic simple gastritis, but that there is no essential connection between these processes is proven by the infrequency of cirrhosis of the stomach compared with the frequent occurrence of simple chronic gastritis. The prognosis is grave. This disease usually runs a chronic course and terminates by asthenia.

The treatment embraces remedies to palliate irritation of the stomach, abstinence from spirits and other stimulants, careful regulation of diet, and, if there be pyloric obstruction, the means indicated in cases of dilatation of the stomach.

Gastro-Duodenitis. Duodenitis.

In acute gastritis the inflammation, as already stated, may extend into the duodenum. This is also true of subacute and chronic gastritis. But it would appear, from the symptoms, that subacute duodenitis may occur as a separate affection, not connected, on the one hand, with gastritis, nor, on the other hand, with inflammation of the lower portion of the small intestine. The symptoms are, obscure pain, uneasiness or distress occurring some hours after the ingestion of food, that is, after it passes from the stomach into the duodenum, and tenderness below the epigastrium over the site of the affected organ. Duodenitis, occurring either separately, or in connection with gastritis and enteritis, is interesting and important as standing in a causative relation to jaundice. The jaundice is to be explained by obstruction either from swelling of the mucous membrane of the duodenum at the opening of the ductus choledochus, or from an extension of the inflammation into the duct. A plug of mucus is frequently found in the ductus communis near its opening into the duodenum. The treatment is the same as that of subacute gastritis. The affection will again be referred to in the consideration of jaundice.

It is a curious fact, first ascertained by Curling, and confirmed by other observers, that a sloughing ulcer is apt to take place at the upper part of the duodenum, within a few days after the occurrence of a severe burn on the

skin. Perforation may occur under these circumstances. Ulceration of the duodenum, however, is by no means a constant effect of an extensive burn.

Pharyngitis. Tonsillitis. Quinsy. Retro-Pharyngeal Abscess.

Affections of the buccal and guttural portion of the alimentary canal, namely, glossitis, the several varieties of stomatitis, etc., belong to surgery. I shall accordingly pass them by with the exception of a brief notice of pharyngitis. Certain affections of the mouth, prevailing especially in early life, are embraced among the diseases of children, and are considered in treatises devoted to these diseases. Acute inflammation of the pharynx may be limited to the mucous membrane, or associated with inflammation of the tonsils or of the submucous areolar tissue. Associated with inflammation of the tonsils it constitutes the affection called *tonsillitis*, commonly known as *quinsy*. The tonsil on one side only or both tonsils may be affected. Acute tonsillitis generally ends in suppuration ; an abscess forms, and purulent matter, sometimes fetid, and nauseous to the taste, is discharged after a period varying in different cases from two to ten days. It is a very distressing affection in consequence of the pain and difficulty of deglutition. The enlargement of the tonsils, when both are affected, is such that the isthmus of the fauces appears to be closed. The mucous membrane covering the tonsils and the arches of the palate is reddened and swollen. The affection, however, is attended with danger only from the very slight liability to the occurrence of œdema of the glottis. Of this I have met with a single example. An attack of tonsillitis is sometimes attributable to exposure to cold, but it often occurs without any obvious causation. The causation involves a predisposition to the affection, and persons predisposed are apt to experience repeated attacks. The treatment consists of poultices to the neck, or the water-dressing, the inhalation of warm vapor, and anodynes to render the condition of the patient less uncomfortable. Milk is the form of nourishment best taken. When the abscesses point they may be opened, and the patient is thus relieved sooner than if they were left to break. Hypertrophy of the tonsils, requiring their ablation, is not uncommon in early life. This affection is considered fully in works on surgery.

Acute pharyngitis, giving rise to inflammation and suppuration in the areolar tissue between the mucous membrane of the pharynx and the vertebral column, constitutes the affection called *retro-pharyngeal abscess*. The point of departure in the development of this grave affection, however, is rarely, if ever, the mucous membrane ; it may occur, traumatically from the penetration of a sharp piece of bone contained in food, or as secondary to caries of the cervical vertebræ.[1]

Inflammation of the pharynx with an exudation of fibrin, constituting what is called diphtheritic, pseudo-membranous, or exudative inflammation, occurs in connection with two important diseases to be considered in another section, namely, diphtheria and scarlatina.

Simple acute pharyngitis, that is, the inflammation limited to the mucous membrane, or erythematic, and unattended by the exudation of fibrin, is an affection of frequent occurrence. It is one of the forms of "a cold." The inflammation may extend over more or less of the pharyngeal space and fauces. Its extent and intensity are to be ascertained by inspection of the throat, but it sometimes extends upward into the posterior nares, and lower

[1] For an excellent article on retro-pharyngeal abscess, with a statistical table of 58 cases, by Charles M. Allen, M.D., *vide* N. Y. Journal of Med., Nov. 1851.

in the pharynx than the eye can reach. It occasions more or less pain, especially in the act of swallowing, and the patient is annoyed by a constant disposition to swallow. At first the inflamed parts are dry, but, after a time, a secretion of mucus takes place, and this provokes efforts at hawking and expuition. If the inflammation extend low in the pharynx, coughing is excited. The cough is of a peculiar character, easily recognized and distinguished as a throat-cough, the forcible current of expired air being brought to bear on the pharynx. The limitation of the inflammation to the pharynx, or its non-extension into the larynx, is shown by the absence of huskiness or hoarseness of the voice.

The tonsils sometimes present a deposit of a white material in patches of greater or less size. This material consists of epithelial cells and pus-cells, mixed often with some granular matter and low vegetable organisms. The deposit extends into the follicular depressions. The condition is inflammatory, and is called follicular tonsillitis. These white patches have a resemblance to diphtheritic exudation, and it is important to discriminate between the two. The follicular secretion forms a pultaceous deposit, not a membraniform layer like the deposit of fibrin, and cannot be removed in strips like the latter. The patches are more prominent than those formed by a layer of fibrin, and their borders are more abruptly defined. They are more easily removed than patches of fibrin recently exuded, and they disappear spontaneously more quickly. Finally, on close inspection, the secretion will be seen to dip into the follicular depressions. The follicular deposit occurs without any abrasion of the mucous surface, but it is common for patients to consider the patches as ulcers.

Simple acute pharyngitis occurs as an epidemic affection, sometimes prevailing greatly and widely. It prevailed to a considerable extent in this city (New York) during the spring of 1864. The clinical history shows the affection to be a form of fever rather than simply a local inflammation. This was manifestly true of an epidemic which I studied in the western part of this State in 1857. From the results of an analysis of twenty-three recorded cases of that epidemic, the following conclusions were deduced: "The disease was an epidemic fever characterized by mild erythematic inflammation of the fauces as a constant local complication. Its character as essentially a fever is established by the febrile movement being in a marked degree out of proportion to the local affection; in other words, evidently not being symptomatic of the latter, and by its running a definite although a brief career. It was a fever of from three to five days' duration. Its epidemic character is sufficiently apparent. It prevailed extensively for about two months, reaching its acme gradually, declining gradually, and at length disappearing, affecting both sexes and different ages without notable discrimination. As an epidemic fever, its symptomatic features were very uniform. The affection of the fauces constituted the only positive character aside from the brief duration of the febrile career. The other symptoms uniformly present were only those incident to febrile movement, and the symptoms observed in a few cases only were incidental events, not intrinsic elements of the disease. The small white patches in the throat observed in a few cases do not establish any relation to the affection known as diphtheria. These were evidently due to follicular secretion. The occurrence of several cases repeatedly in the same family does not suffice to prove that the disease was propagated by contagion, since this fact is explicable on the supposition of the patients being equally exposed to an epidemic influence, and there being a marked discrepancy in the intervals separating the cases successively occurring in the same family."[1]

[1] Buffalo Medical Journal, vol. xii. p. 718.

In the report from which the foregoing conclusions are quoted, facts are given which show conclusively that the affection was not scarlatina. It resembled influenza, save that the pharyngeal, and not the bronchial, mucous membrane was the seat of the local manifestation. It may be a question whether an epidemic fever with simple pharyngitis be not a form of influenza, or of the affection called epidemic erysipelas, popularly black tongue.

Simple pharyngitis, occurring as a sporadic disease, or as the anatomical characteristic of an epidemic fever, is a mild disease, having little or no tendency to end fatally. Œdema of the glottis is an accident which may occur, but it is extremely infrequent. I have met with one example of its occurrence in a case of sporadic pharyngitis. The therapeutical measures indicated are, mild purgation, followed by anodyne remedies, quinia and the chlorate of potassa. Gargles of the chlorate or the nitrate of potassa may be employed, and to allay the dryness and irritation of the throat, a mucilaginous liquid, or glycerine, may be taken frequently in small quantity, or small pieces of gum allowed to dissolve in the mouth. Caustic or stimulating applications to the inflamed membrane are not called for.

Subacute pharyngitis, not becoming chronic, is very common, and is generally treated without the advice of a physician. It is generally sufficient to supply the absence of mucus, before secretion takes place, by mucilage or glycerine. Lumps of sugar soaked in salad-oil and allowed to dissolve in the mouth is a simple mode of palliating the local irritation. If other measures appear to be called for, those appropriate to the acute affection may be employed.

Chronic pharyngitis, in this country, is an extremely common affection. It is commonly known as "the catarrh." It is generally a subacute affection at the beginning, and is developed imperceptibly, so that, in most cases, when patients first come under medical observation, it has existed for a considerable period. The membrane is more or less reddened and thickened; the surface in some cases is smooth, but oftener presents a granulated or mammillated appearance especially marked on the posterior wall of the pharynx. In the latter cases the pharyngitis is said to be follicular, but it is not certain that the prominences which occasion the granular appearance are seated at the follicles. Granular pharyngitis is a better term. Adhesive mucus is sometimes seen sticking to the part, when the throat is examined. This inflammation often extends to the posterior nares. It may extend around the top of the larynx, but it has no tendency to pass into the laryngeal cavity. The mucous membrane around the openings of the Eustachian tubes may be swollen, and the inflammation, in certain cases, extends into the tubes. As a consequence, deafness is not uncommon from obstruction of these tubes, requiring their catheterization.

The surface of the tonsils in some cases presents white or ash-colored bodies varying in size from that of a pin's head to a pea, either wholly imbedded in, or in part projecting from, the mouths of the follicles. I have met with cases in which the tonsils were very thickly studded with these projecting bodies. If removed mechanically, as may easily be done, they are sometimes quickly renewed. If not understood, the striking appearance of the throat in these cases may lead to the apprehension that the affection is more important than it really is. In these cases the name follicular tonsillitis is more appropriate.

Chronic pharyngitis in some persons occasions but little inconvenience. It is often found when the patient makes no complaint of any trouble in the throat. In other cases, it occasions more or less annoyance. An uncomfortable sensation is felt in the throat. The presence of adhesive mucus

excites efforts of hawking and coughing. The proximity of the inflammation to the larynx may give rise to a dry, hacking cough. The voice becomes slightly hoarse after considerable use in speaking or reading. The use of the voice is followed by a sense of fatigue in the vocal organs.

The affection is much more frequent in men than in women. It occurs most frequently after puberty, and in middle life. From its frequent occurrence among the clergy, it has been called *clergyman's sore-throat;* but it is by no means peculiar to the clergy, occurring oftener in persons of other callings. It occasions more inconvenience to clergymen than to others, from the necessity which they are under of using the voice in public speaking, and they are apt to be apprehensive lest it may incapacitate them from preaching. It may be doubted whether the use of the voice leads to the affection. It occurs especially among persons of sedentary habits who suffer from the wear and tear of continued application, without physical and mental relaxation. The number of persons is very large in this country who overtask the powers of the system by steady labor in the office, the counting-house, or the workshop, continued without intermission for many years, giving no time whatever to recreation. It is among those who in this way violate the laws of health that this affection prevails. It seldom occurs among the so-called laboring classes, and it is much more frequent in cities than in the country. It is accompanied with symptoms denoting impairment of the general health. Patients complain of debility and a want of their accustomed energy; they are generally depressed in spirits and have forebodings of loss of health; they are very apt to fancy the existence of some serious disease, especially pulmonary consumption, and it is sometimes difficult to convince them that the latter disease does not exist. Dyspeptic ailments frequently co-exist. Palpitation of the heart is not uncommon.

The affection tends to continue. It is usually long persisting. In many of the cases which I have seen it had existed for many years. But there is no tendency to eventuate in an affection of the air-passages, or in tuberculous disease. Patients with this affection, indeed, rarely become tuberculous; its existence is, to some extent, evidence of the non-existence of phthisis.

The treatment, to be effective, must have reference to the system. Topical applications alone are rarely efficacious. A fair trial of them, however, should be made. The nitrate of silver in strong solution (20 or 30 grs. to the ounce) in some cases, especially of the granular variety, is highly useful. It is to be applied by means of a probang, mop, or large camel's-hair-pencil brush. A solution of tannin is often of service. The chloride, iodide, or sulphite of zinc, and iodoform are recommended. Inhalations are not appropriate; they carry the medicated application too far. On the other hand, gargles are of little use; they do not carry the application far enough. Projecting a spray of medicated solutions into the throat is an efficient mode. Applications to the posterior nares may be made by means of the nasal douche; if made by injecting from the fauces, there is danger of the fluid passing into the Eustachian tubes and causing otitis media. The constitutional remedies which exert a curative influence in certain cases are the iodide of potassium, the bromides, the chlorate of potassa, and the hydrochlorate of ammonia. Alteration of the habits of life is first in importance. Relaxation, recreation, and out-of-door life are far more efficacious than medicines, and the latter are of little use without the former. When circumstances permit, relinquishment of business, for a time, for travel or rural occupations, is of signal benefit. Tonic remedies may often be advantageously conjoined with proper hygienic management. Tonics, to be efficacious, should be continued for a long period, and the form of tonic changed from time to time. The diet should

be nutritious. The object of treatment, in short, is to restore the general health.

The diagnosis of chronic pharyngitis is, of course, sufficiently easy. Inspection is alone necessary. But it is important to discriminate simple chronic pharyngitis from that dependent on syphilis. The latter is to be suspected from the local appearances (ulcerations and the so-called mucous patches), and discriminated by these appearances in conjunction with other secondary syphilitic phenomena, together with a knowledge of the fact of syphilis having existed. The rhinoscope or pharyngeal mirror is of service in the inspection of the naso-pharyngeal cavity, and especially the condition of the mouths of the Eustachian tubes.

In chronic follicular tonsillitis, the matter which accumulates in the follicles may be ejected by coughing, in the form of round, solid pellets which are sometimes supposed to be tubercles or pulmonary calculi. They are to be distinguished from the latter by being crushed, not fractured, by pressure, by being unctuous to the touch, and emitting, when crushed, a fetid odor. The annoyance from chronic pharyngitis is often much enhanced by patients concentrating their attention upon it. They sometimes fall into a habit of constant hemming or "clearing the throat," which is not only fatiguing to themselves, but extremely disagreeable to others. The importance of making an effort to avoid such a habit, and to think of the affection as little as possible, is to be inculcated.

Inflammation and other Affections of the Œsophagus.

Inflammation of the œsophagus (œsophagitis), acute, subacute, or chronic, is extremely rare. As an idiopathic, non-traumatic affection, it may be said almost never to occur. It may be produced by the ingestion of corrosive poisons, by the irritation of foreign bodies, and by an extension of inflammation from adjacent parts. In some cases of diphtheria the diphtheritic affection extends into the œsophagus, and ribbon-like pseudo-membranes are sometimes expelled. The eruption in some cases of smallpox occurs in this situation.

The diagnostic symptoms are pain and soreness localized in this situation, and especially manifest in the acts of deglutition. The passage of an œsophageal sound occasions pain, and, on its withdrawal, mucus or pus may be adherent to it. The latter are evidence of œsophagitis only when carcinoma of the cardiac orifice of the stomach is excluded by the absence of obstruction.

The rational indications for treatment are the nourishment of the patient by a bland liquid diet, of which milk should be the basis, and, if this occasion pain, substituting therefor rectal alimentation.

Stenosis, caused by morbid growths, cicatrized ulcers, etc., is ascertained by exploration with the sound, in conjunction with the evidence of obstruction to the ingestion of food. Primary carcinoma occurs in the œsophagus. The consideration of these affections belongs to surgery. In this category belong foreign bodies, the presence of vegetable and animal parasites, dilatations, and diverticula. Rupture of the œsophagus is an occasional accident.[1]

Obstruction may depend on compression by an aneurism or a tumor of some kind. The obstructing cause in these cases is generally apparent. The fact of obstruction in a person over forty years of age, should always suggest exploration for the signs of an aneurismal tumor. Rupture of aneurisms

[1] *Vide* case reported by Prof. Fitz, Am. Journ. of Med. Sciences, Jan. 1877.

sometimes takes place into the œsophagus. Ulcers having the characteristics of gastric ulcer may occur in the lower end of the œsophagus.[1]

Perforation from the presence of a foreign body may establish a communication with the pericardial or the pleural cavity; it may tend to subcutaneous emphysema of the neck, and the escape of fluids swallowed into the areolar structure. Cases have been reported of softening and perforation of the lower portion of the œsophagus by the gastric juice.

Paralysis of the muscular coat, in connection with that of the pharyngeal muscles, may occur after diphtheria, in connection with bulbar paralysis, and in some cases of general paralysis and of cerebro-spinal multiple sclerosis. *Spasm* of the œsophagus (œsophagismus), of transient duration, is one of the hysterical manifestations. Irrespective of that connection, it may cause obstruction for hours and days. In a case reported by Dr. J. J. Henna, which I saw in consultation, complete obstruction from spasm existed for eight days, and was instantly and permanently removed by a single introduction of a sound.[2]

For an exhaustive account of the diseases of the œsophagus, with bibliographical references, the reader is referred to Ziemssen's Cyclopædia, volume viii. of the American edition.[3]

Parotiditis. Mumps.

The affection commonly known as mumps may be appropriately noticed in this connection, as seated in an organ accessory to the buccal cavity. The disease is infectious and contagious. It therefore involves a constitutional morbid condition and a special causation. It often prevails as an epidemic. The most marked local affection in this disease is inflammatory swelling of the parotid gland and surrounding connective tissue. As the disease rarely terminates fatally, little is positively known of the anatomical changes in the gland. The interstitial tissue of the gland is believed to be infiltrated with serum, and to contain a few emigrant white blood-corpuscles. The epithelium of the acini and ducts of the gland may be supposed to swell up and undergo parenchymatous degeneration. An inflammatory œdema of the connective tissue about the gland exists in most cases. More serious structural changes than those described are not supposed to exist, as the restitution of the gland and of the surrounding tissues to their normal condition occurs with such ease and rapidity. Virchow teaches that the inflammation has its point of departure in the ducts, and is propagated from simple inflammation of the buccal mucous membrane (stomatitis). According to this view, the infectious agent gains access to the gland from the mouth by Steno's duct. A similar coincident inflammation of the submaxillary and sublingual glands is not infrequent. Cases have been described in which these glands were involved and the parotid escaped. Erythematous inflammation of the mouth and pharynx is frequently present in cases of epidemic parotiditis.

According to Trousseau, the period of incubation of mumps is from ten to fourteen days. Lucke estimates it as reaching seventeen to eighteen days. The disease is frequently ushered in by a slight chill or by chilly sensations, and in its progress it may be accompanied with moderate febrile movement, diminished appetite, pain in the head and general malaise. A certain degree of febrile disturbance usually precedes for a short time the enlargement of the parotid gland, and generally subsides before the swelling fully disappears.

The swelling usually begins in one gland, but, with few exceptions, both glands become involved, although the one first affected suffers the most. The amount of swelling in the site of the parotid gland varies in different cases; if considerable or great, it causes a notable change in the physiognomy. The skin generally is not discolored, but there may be an inflammatory blush. The mucous membranes of the mouth, pharynx, and conjunctiva are often moderately inflamed. Pain upon moving the jaws and difficulty in swallowing are experienced. The disease continues from four or five days to two weeks. The swelling, pain, and soreness gradually subside and disappear. The inflammation has no tendency to suppuration, nor to continue in a chronic form. An abundant perspiration sometimes takes place at the time of convalescence. In males, after the age of puberty, one, rarely both, of the testicles sometimes may become inflamed. This orchitis is usually called metastatic. When it appears the swelling in the parotid sometimes subsides. This so-called metastatic orchitis is not very frequent. It seems to be more frequent in some epidemics than in others. Most of the statistics bearing on its frequency have been derived from military practice. The largest compilation from this source has been made by Granier.[1] In 495 cases of parotiditis in soldiers, orchitis occurred in 115, that is, in twenty-four per cent. of the cases. Atrophy of the affected testicle often follows this inflammation. According to Granier, atrophy occurs in forty-four per cent. of the cases of orchitis, and in ten and one-third per cent. of the cases of parotiditis. The shorter the duration of the orchitis, the less probability is there of atrophy of the testicle. In females a similar inflammatory swelling of the mammary gland and of the ovary has been observed as an exceptional occurrence. When parts other than the parotid are involved, this is not, strictly speaking, from a metastasis, but from the operation of the same internal morbid condition which occasions the inflammation of the parotid. In very rare instances epidemic parotiditis is of an unusually severe character. The fever and constitutional disturbance may be exceptionally high. Maniacal delirium and other severe cerebral symptoms have been observed. The patient has been known to sink into a typhoid state. Convulsions sometimes occur in children; facial spasm is less infrequent. The gland has been known to suppurate in this disease. These occurrences, however, are so rare as to be more curiosities than of practical importance.

The communicability of this disease is generally admitted, but it has been denied by some writers of high authority, for example, by Valleix. Its communicability is not inconsistent with its prevalence as an epidemic disease. This is true of diseases which are exclusively propagated by contagion, *e. g.*, smallpox. Persons between twenty and thirty years of age are most susceptible to the infectious miasm, but it occurs not infrequently under puberty. Males are more susceptible than females. It is one of the diseases which affect the same person but once.

The prognosis is generally favorable, the complications and accidents which have been mentioned being exceptional. Except that it occasions considerable discomfort, the disease, in most cases, is trivial. In the way of treatment, it claims only soothing embrocations, and the application of flannel, cotton batting, or wool to the neck, with some anodyne remedy if the pain be considerable. Bloodletting, purgation, or other of the so-called antiphlogistic

[1] Granier, Lyon méd., No. 26, 1879.
In Laveran's collection of 432 cases in soldiers, orchitis occurred 156 times. In 32 cases of orchitis observed by Laurens (out of 118 of parotiditis), one testicle alone was affected in 26 cases, and both testicles in 6 cases. In 16 of these cases Laurens observed distinct atrophy within two months.

measures are not indicated. The popular apprehension of danger from "taking cold" in this disease, is based on the idea that, if the affection of the parotid be arrested, a metastasis is apt to take place. There is little ground for this idea, but a patient probably passes through the disease more comfortably by avoiding exertion and exposure.

Parotiditis occurs as an occasional complication of typhus and typhoid fever, pyæmia and pneumonic fever. Under these circumstances it is a widely different affection from mumps. Suppuration takes place in the great majority of cases, the abscesses evacuating either externally or into the meatus auditorius, and frequently there is considerable sloughing of the areolar tissue. As a complication of fever it is attended with much suffering and danger.

Acute suppurative inflammation of the connective tissue around the submaxillary gland, is called by German writers *angina Ludovici*. There is present in the supra-hyoid region diffuse cellulitis, combined often with gangrene and sloughing of the tissues. The inflammation may extend to surrounding parts. The affection is a grave one. The most favorable termination is in abscess. Death occurs from œdema glottidis, secondary pneumonia, or septicæmia. The treatment is mainly surgical.

CHAPTER III.

STRUCTURAL AFFECTIONS OF THE STOMACH.

Softening. Gastric Ulcer. Carcinoma of Stomach. Dilatation of Stomach. Degeneration of the Gastric Tubes. Waxy Degeneration of the Stomach.

HAVING considered the inflammatory affections of the mucous membrane lining the different sections of the alimentary canal, the structural affections of the stomach and intestines next present themselves for consideration. Directing attention, first, to the stomach, the following are the structural affections to be noticed: Softening, ulceration, carcinoma, dilatation, lesions of the gastric tubules, and waxy degeneration. These several affections will be briefly considered in the order in which they have just been enumerated. For a fuller consideration of these affections than is consistent with the scope of this work, the reader is referred to works on morbid anatomy and treatises devoted specially to diseases of the stomach.

Softening of the Stomach. Gastromalacia.

Softening of the mucous tunic of the stomach has been already mentioned as one of the anatomical characters of gastritis. In the same connection, the importance of not considering mere softening as an evidence of inflammation was dwelt upon. At autopsies, softening of the mucous membrane of the fundus is very often found. Softening may, however, be much more extensive. Not only may it involve the entire inner surface of the stomach, but it may extend in depth so as to affect the remaining coats of the stomach, and it

may even lead to perforation of the stomach and the escape of its contents. Nor does the process always stop there. The adjoining organs may be attacked, and undergo a similar softening. Thus the liver may be partially destroyed, or the diaphragm may be perforated and the contents of the stomach be found in one of the pleural cavities. There has been much controversy as to the nature of this softening, but it is now admitted that, in the vast majority of cases, it is a post-mortem occurrence due to self-digestion. It has been rendered probable by the experiments of Pavy that the stomach is protected during life from self-digestion by the alkalinity of the blood circulating in its walls.[1] The alkaline blood, which flows in an especially rich network of capillaries in the superficial layers of the mucous membrane, neutralizes the acid of any of the gastric juice which may penetrate the mucous membrane. With death, the neutralizing influence of the circulating blood ceases. If the stomach now contain a sufficient quantity of gastric juice, and if the temperature be suitable, there is nothing to prevent the digestion of this organ, and the extension of the digestive process to surrounding parts. John Hunter was the first to establish the fact that, under certain circumstances, the stomach undergoes digestion after death. Self-digestion sufficient to produce perforation of the stomach is not a common occurrence. It has been met with most frequently in nursing children who die during digestion, especially in those dead of cholera infantum. It has been observed also in adults both in cases of sudden death and after exhausting disease. A warm temperature and an abundance of acid in the stomach are the conditions most favorable for self-digestion. The acid may be produced by fermentation of milk, amylaceous substances, and other materials. As the contents of the stomach naturally gravitate to the fundus, this is the part most frequently affected. In many instances the lower portion of the œsophagus has been affected, and it may be the only part notably softened. The digested portions present a soft, pulpy, gelatinous appearance, and hence the names pultaceous softening and gelatiniform softening employed by Louis and by Cruveilhier, who regarded the change as an ante-mortem occurrence. The color varies with the amount of blood pre-existing in the softened tissues. If the parts contained a large quantity of blood, the color is brown or blackish, otherwise it is whitish. Hence white or gray softening and brown softening are distinguished. The former is the one generally met with in children, and is always a cadaveric alteration. The softened parts have an acid reaction, and are free from the odor of putrefaction. If perforation take place, the aperture is a ragged hole with pulpy edges which present no signs of inflammation.

While it is agreed that in the great majority of cases digestive softening of the stomach is a post-mortem event, there are good authorities who admit the possibility of its occurrence during life. Rokitansky, even in the last edition of his great work on pathological anatomy, contended that in a certain number of these cases it was produced, or at least began, during life. Virchow, although less positive in his statements, is unwilling to deny the possibility of the occurrence of this form of softening during life. The only strict proof of the development of gastromalacia during life, would be afforded by a case in which the softening had advanced to perforation, the symptoms of this perforation having been recognized during life, and its existence, with the characteristic

[1] This explanation is not without some serious objections. It is not possible to explain in the same way the fact that the alkaline pancreatic juice does not digest the pancreas or the alkaline intestinal juice the intestinal mucous membrane. It must be admitted that we possess no thoroughly satisfactory explanation of the absence of self-digestion of the stomach during life. A critical and experimental examination of Pavy's theory has been recently published by Samelson, Die Selbstverdauung des Magens, Jena, 1879.

changes of digestive softening, attested after death. Hoffmann[1] has reported two cases in which softening and perforation (in one case of the œsophagus and in the other of the stomach) were found after death, and were believed, from the symptoms, to have occurred during life. He refers also to one of Virchow's cases in which a similar diagnosis seemed probable. Mayer[2] also reports a case from Ziemssen's clinic, which he considers convincing as regards the undoubted occurrence of simple softening and perforation during life. In these cases the softening was of the brown variety, and seems to have been preceded by hemorrhages in the walls of the stomach. The patients were already much prostrated by pre-existent diseases. If vital gastromalacia ever occur, it is probably only as an accompaniment of diseases in which the powers of life are greatly enfeebled, and in which the resistance of the mucous membrane to the action of the gastric juice is lessened by the presence of hemorrhages or of other pathological changes. An abnormally acid composition of the gastric fluids may also be an element in the causation, as was especially emphasized by Rokitansky.

Gastric Ulcer.

The form of ulcer to be here considered constitutes one of the most frequent and dangerous of the diseases of the stomach. It is to be distinguished from certain ulcerations which sometimes occur in connection with inflammation of the stomach, namely, the so-called catarrhal ulcers, follicular ulcers, and superficial hemorrhagic erosions. To these conditions, as well as to ulcerations produced by corrosive poisons, reference has already been made. Genuine tuberculous ulcers occur in the stomach, but they are very rare, and require no further mention.

To the form of ulcer now under consideration various epithets have been applied, such as simple (in distinction from cancerous), chronic (a term not always applicable), round, perforating, eroding, digestive (ulcus ventriculi simplex, chronicum, rotundum, perforans, corrosivum, ex digestione). Simple ulcer of the stomach presents certain anatomical peculiarities which are met with elsewhere only in a similar form of ulcer in the lower part of the œsophagus and in the upper part of the small intestine.[3] The most marked of these peculiarities is, that in its early stages the ulcer presents no evidences of inflammation in its base or its edges. The shape of the ulcer is round or oval, sometimes, but rarely, irregular from the coalescence of two or more ulcers. The floor of the ulcer lies usually deeper than the mucous coat. From its tendency to extend in depth, the ulcer is called perforating. The floor is not infrequently the muscular tunic; it may be the serous coat, or, if the ulcer has perforated the walls of the stomach, and adhesions have formed, the base of the ulcer may be occupied by some of the adjacent viscera, such as the pancreas or liver. As the ulcer extends in depth, each successive tunic of

[1] Hoffmann, Virchow's Archiv, Bd. 44, p. 352, 1868.

[2] Mayer, Deutsches Archiv für klinische Medicin, Bd. ix., p. 105, 1871. This case was observed by Leube, and is also considered conclusive by him He reports it in full in Ziemssen's Cyclopædia of the Practice of Medicine, American Translation, vol. vii. p. 262. Thorspecken (Deutsches Archiv, Bd. 23, p. 621, 1879) has also published a not altogether convincing case of ante-mortem gastromalacia. Perforation of the stomach from self-digestion is not to be confounded with the destructive effects of corrosive poisons, and knowledge of the characters which distinguish the former is highly important in making autopsies after sudden death in cases involving a suspicion of poisoning.

[3] This is true unless the rare variety of ulcer described by Clarke and by Klebs as ulcus corrodens uteri—corroding ulcer of the cervix uteri—be included in this category. Consult Klebs, Handbuch der pathologischen Anatomie, Bd. I. p. 873.

the stomach is invaded in less extent than the preceding; the ulcer thus acquires a characteristic funnel-shape, the large opening being in the mucous membrane, and the apex directed towards the peritoneum. The successive layers can sometimes be recognized as strata or steps in the wall of the ulcer. This funnel-shaped appearance is not always present. The edges are sometimes abrupt instead of sloping. If the ulcer be recent, its edges are smooth and clean-cut like those of a hole punched out of the mucous membrane; they may be infiltrated with blood, but are not swollen by inflammatory exudation. The base may be smooth, or soft and pulpy, and it may also have a hemorrhagic aspect. More frequently old ulcers are found, in which the edges are somewhat thickened and indurated by the growth of fibrous tissue. The floor in old ulcers is usually smooth, pale, and hard. Chronic catarrhal gastritis is not infrequently present. The size of the ulcer varies much in different cases. The average size is perhaps that of a silver dime or quarter of a dollar. The ulcer may be very minute. In two cases reported by Murchison pore-like holes, from one to two lines in diameter, were found, which had penetrated one of the gastric arteries and produced fatal hemorrhage. A similar case has been reported by Reid.[1] On the other hand, the ulcer may be as large as the palm of the hand, and may extend along the lesser curvature from the pyloric to the cardiac orifice.[2] As a rule, only a single ulcer is found, but it is not a great rarity to find two or more ulcers (according to Brinton, in 21 per cent. of the cases). Still less infrequent is it to meet with the cicatrices of old ulcers. Sometimes ulcers are found opposite each other on corresponding parts of the stomach. The most frequent seat of gastric ulcer is in the pyloric region on the posterior surface and in the immediate neighborhood of the lesser curvature.[3] Ulcers of the anterior surface are much rarer, but more dangerous, as will be explained presently. The microscopic examination of ulcers still progressing, shows in their base and edges a granular substance which is the result of molecular disintegration of the surrounding tissue. It is by a process of molecular necrosis that the ulcer extends. In rare instances, according to Leube, granulation-tissue may be present in the wall of the ulcer. In the ulcers with hard, thickened edges, these, as well as the base, are occupied by fibrous tissue containing fusiform and round cells; the bloodvessels in this tissue present thickened walls and diminished calibre; they may contain thrombi. Newly-formed connective tissue may extend for some distance into the surrounding mucous membrane and compress the tubules which may be thereby distorted and even obliterated. Simple ulcer may be complicated by cancer of the stomach. In fact, some writers believe that ulcer may even predispose to the development of cancer.

Ulcer of the stomach not infrequently heals by cicatrization; in fact, cicatrices are found oftener than open ulcers. The resulting cicatrix is usually a whitish stellate scar, attended with puckering of the adjacent mucous membrane. If the ulcer be large and deep, cicatrization may cause considerable, and even extreme, deformity of the stomach. Thus the stomach may be constricted so as to present an hour-glass shape. Stricture of the pylorus, with consequent dilatation of the stomach, may be caused by cicatrization of an ulcer. But, instead of cicatrizing, the ulcer may penetrate all of the coats of the stomach. When the ulcer is situated on the posterior surface of the

[1] Reid, Buffalo Medical Journal, vol. ii. p. 641, 1846.

[2] Cruveilhier has described an ulcer $6\frac{1}{2}$ inches long and $3\frac{1}{3}$ wide; Law, one measuring 6 by 3 inches.

[3] According to Brinton's admirable analysis of 220 cases, in 86 the ulcer was situated at the posterior surface, in 56 at the lesser curvature, in 32 on the pylorus, in 13 on both the anterior and posterior surfaces, often in opposite positions, in 10 on the anterior surface only, in 5 on the greater curvature, and in 4 in the cardiac pouch

stomach, as is usually the case, a localized peritonitis over the seat of the ulcer generally leads to the formation of adhesions with surrounding organs, so that, when perforation is effected, the floor of the ulcer is formed by some part adjacent to the stomach. Sometimes, however, the development and the progress of the ulcer are so rapid that time is not allowed for the formation of adhesions, and the contents of the stomach escape into the peritoneal cavity. It is a noteworthy fact that ulcers on the anterior surface, although the least frequent, are the most liable to perforate without protective adhesions. The explanation of this peculiar danger lies in the active movements of this part of the stomach and its unfavorable relations to surrounding parts. The pancreas most frequently forms the floor of ulcers situated on the posterior surface, but the stomach may also become agglutinated to the liver, the spleen, the diaphragm, lymph-glands, etc. The ulcer may continue to extend into the surrounding organs which form its base. The pancreas usually offers considerable resistance to the progress of the ulcers, but the liver is not infrequently invaded. The funnel-shaped appearance is not preserved in the organs secondarily involved. On the other hand, cavities of considerable size may be formed, which communicate by a small opening with the stomach. The reactive inflammation in organs invaded by gastric ulcer, leads to the formation of fibrous tissue, and sometimes, particularly in the liver, to abscesses. Fistulous communications of the stomach with adjacent parts may be formed. Thus the ulcer may open into the colon, the duodenum, or some other part of the intestine, into the pleural cavity, the lungs, the gall-bladder. Gastro-cutaneous fistulæ may be produced, but they are very rare. The most frequent are gastro-colic fistulæ. If the ulcer opens into the peritoneal cavity —and this accident may take place even after adhesions are formed—peritonitis ensues if the patient live long enough. Death sometimes occurs suddenly from perforation of the stomach, and is attributed to paralysis of the heart from shock. The peritonitis following perforation is usually general. It is sometimes, however, localized, in consequence either of the slow escape of the gaseous and fluid contents of the stomach through a small opening, or of the formation of previous adhesions. On page 154 reference has been made to subphrenic abscesses containing air and simulating pneumo-pyothorax. The external opening in the stomach is usually round, and its edges are sharp and well defined in cases of perforation.

The hemorrhages, which constitute one of the chief dangers to life in gastric ulcer, may proceed from capillaries and small vessels in the walls or base of the ulcer, or they may come from erosion of a large artery or vein. In cases of profuse fatal hæmatemesis, an eroded artery will generally be found in the floor of the ulcer. The ulcerated artery may be either one of the arteries of the stomach, or an adjacent vessel, as the splenic. Gastric ulcer has been known to perforate the portal vein, and in more than one instance a simple or a suppurative pylephlebitis has been produced by this disease.

The *pathogenesis* of simple ulcer of the stomach has been a subject of much experimentation and discussion. The absence of inflammation, and the fact that this variety of ulcer is only met with in the lower part of the œsophagus, the stomach, and the upper part of the small intestine, early suggested the view that it is produced by the solvent action of the gastric juice, and this is the opinion now generally entertained. Hence the names peptic ulcer, digestive ulcer, ulcus ex digestione, are sometimes employed. In the preceding article was stated Pavy's view, which is widely accepted, that self-digestion of the stomach is prevented during life by the constant flow of alkaline blood in the rich capillary network of the gastric mucous membrane. If this view be adopted, it must be assumed that the primary cause of simple gastric

ulcer is to be found in some local disturbance of the circulation in the gastric mucous membrane. As to this, also, most writers are agreed. As to the nature, however, of the change thus interfering with the circulation, there is the widest diversity of opinion. An absolute basis of fact is lacking for nearly all the theories propounded to explain the diminished resistance of the mucous membrane to the action of the gastric juice. The anatomical investigation of the ulcer, as a rule, furnishes little or no clue to its primary cause. The following conditions have been assigned as causes of gastric ulcer by interfering with the circulation and consequently diminishing the alkalescence of circumscribed portions of the wall of the stomach: embolism and thrombosis of branches of the gastric arteries; thrombosis of the corresponding veins; diseases of the coats of the same vessels, especially atheroma, fatty degeneration, and amyloid degeneration; spasm of the arteries, causing anæmia of the districts they supply, spasm of the muscular coat of the stomach, compressing the veins and leading to hemorrhages; obstructions in the portal circulation, inducing chronic congestion and hemorrhages from the gastric veins; hemorrhages into the wall of the stomach from rupture of the vessels incident to injuries, vomiting, ingestion of corrosive substances, increased blood-pressure, and aneurismal and varicose dilatations; inflammatory infiltration compressing the bloodvessels. Disturbed nervous influence has also been adduced as a cause.[1] Böttcher's view, that gastric ulcer is of mycotic origin and produced by the action of micrococci, has met with no confirmation. Finally, increased acidity of the gastric juice has been thought to be an element in the causation of digestive ulcer. It would lead too far to attempt a criticism of these different theories. The embolic origin is naturally suggested by the funnel shape of the ulcer corresponding to the wedge-shaped area of distribution of branches of the gastric arteries; but this theory is almost wholly devoid of anatomical support. No embolus in a gastric artery is found in ulcer of the stomach, and in the majority of cases there is no source for an embolus.[2] Gastric ulcer is by no means a frequent occurrence in disease attended by embolism in various parts of the body. If a thrombus be found in a vessel near a gastric ulcer, it is as proper to consider it the effect as the cause of the ulcer. The most plausible view, and the one which has the most numerous supporters is, that a considerable number of ulcers of the stomach are produced by hemorrhagic infiltration of a circumscribed portion of the wall of the stomach. It is to be noted, as pointed out especially by Axel Key, that the hemorrhage must involve more than the superficial layer of the mucous membrane, must extend probably to the deeper and less vascular tissues. Superficial hemorrhages are followed by superficial erosions, the extension of which in depth is arrested by the great vascularity of the mucous membrane. The mode of production of hemorrhagic erosion is thus similar to that of simple ulcer. The causes of these deeper hemorrhages are doubtless various, and include

[1] In support of this view have been cited the experiment of Frerichs, who found an ulcer of the stomach in a cat after division of the splanchnic nerves and of the cœliac axis, and the experiments of Ebstein, who, by injuries to the brain and cord in animals, produced ulcers upon a hemorrhagic base. A not very appropriate comparison has also been made between gastric ulcer and ulcer of the cornea after section of the trigeminus.

[2] Merkel's case is the only one reported, to my knowledge, in which an embolus was found leading to an ulcer. This was an ulcer of the duodenum. The aorta was atheromatous, and contained thrombi. Emboli were found also in the kidney. Wien. med. Presse, Nos. 30 and 31, 1866. The branches of the gastric artery do not belong to the terminal system (see Part I. p. 31). In conformity with this, Roth observed neither hemorrhagic infarction nor ulceration after ligature of branches of the gastric arteries. On the other hand, Panum found both these effects following the introduction of wax emboli through a tube thrust into the femoral artery and extending into the neighborhood of the stomach.

many of the causes of ulcer which have been enumerated. Perhaps spasm of the muscular fibres of the stomach attendant upon cardialgia and vomiting should be especially mentioned. As pointed out by Rindfleisch, the veins pass through the muscular tunic of the stomach surrounded by loose connective tissue, and from their thin walls and looser envelopment, would be compressed more than the arteries by contraction of the muscular coat of the stomach. But while considering hemorrhage in the coats of the stomach as a probable, and perhaps frequent cause of ulcer, it is not necessary to consider it the only cause or to deny the efficacy of other causes which have been cited, the importance of which, with our present knowledge, is less evident.

Gastric ulcer is not an infrequent affection. Brinton's researches showed that it is found after death in an average of five per cent. of persons dying from all causes. Statistics appear to show a considerable variation in its frequency in different situations. In Prague, where the largest number of cases was examined with reference to this point, ulcer was found in 3 or 4 per cent.; in Berlin and Erlangen the proportion was $4\frac{1}{2}$ per cent.; in Jena it was 10 per cent.; and in Copenhagen, 13 per cent. The large percentages were based on an examination of a comparatively small number of cases.

The clinical history embraces, as the most prominent symptoms, pain, tenderness on pressure, vomiting, and hemorrhage from the stomach. These are the important symptoms in a diagnostic point of view. Pain is rarely wanting. It is burning or gnawing in character, coming on directly, or soon after, the ingestion of food, and continuing until the contents of the stomach have either passed into the duodenum or been ejected by vomiting. The quickness with which the pain follows the ingestion of food, is a diagnostic point; if due to simple indigestion or neuralgia, it generally occurs after a greater or less interval from the time of taking food. It is situated at, or near, the epigastrium, and is generally confined to a small space. A similar gnawing pain in the back, between the shoulders, is not uncommon. The probable cause of the pain is irritation of the ulcerated space by the contact of the ingesta and the gastric juice. The pain from this cause is especially marked after the ingestion of stimulating articles of food or drink, and when, from indigestion, the contents of the stomach undergo chemical changes. Pain may also be caused by circumscribed peritonitis, and by the traction of adhesions which have resulted from peritoneal inflammation. The latter causes may account for the exceptional occurrence of pain irrespective of the ingestion of food. The pain caused by the action of the gastric juice is felt directly after eating, because the secretion of the juice is excited by the presence of food in the stomach. The pain is sometimes absent for several consecutive days. It is affected by the position of the body, being in some cases increased by lying on the back, and relieved by bending forward; in other cases the reverse is observed. The explanation is afforded by the situation of the ulcer on the posterior or the anterior wall of the stomach. As in the majority of cases the ulcer is on the posterior wall, relief is oftener obtained by bending forward than by recumbency on the back. Tenderness on pressure over the epigastrium is almost invariably present, confined, like the pain, within a small area, and varying considerably in degree in different cases. Vomiting is a very frequent, but not a constant, symptom, occurring after a period from the time of taking food varying in the different cases, the act of vomiting usually not violent but complete, and the ejection of the contents of the stomach followed by notable relief of pain and distress. Mucus may be expelled, in more or less abundance, with the ingesta. As respects vomiting, much will depend on the quantity and kind of food ingested. Indigestible and stimulating articles are more likely to provoke it, as well as to increase

pain, than those which are bland and easy of digestion. Hot substances are not as well borne as cold. Hemorrhage, as shown by the vomiting of blood in greater or less quantity, is a symptom of frequent occurrence. The vomiting of blood generally occurs after a meal. The hemorrhage is sometimes so abundant that life is lost from this cause. Cases have been reported in which life was lost from hemorrhage, although no blood was vomited, the stomach being found after death filled with clots. The blood vomited is dark or grumous from the change of hæmoglobin to hæmatin by the action of the gastric juice, provided the vomiting does not immediately follow the hemorrhage. If vomiting quickly follow a profuse hemorrhage, the blood may retain its alkaline reaction and its arterial color. As a rule, simple inspection of the vomited matter suffices to determine the presence or the absence of blood. In cases of doubt, resort may be had to microscopic or spectroscopic examination. Blood-corpuscles, usually much shrivelled, can generally be recognized by the microscope. Sometimes, however, they are so disorganized by the action of the gastric juice that their detection by this instrument is difficult or impossible. In this case the spectroscope will usually afford the desired information. The stools also should be examined with reference to the gross and microscopical appearance of blood, since hemorrhage may take place without vomiting, the blood passing into the intestinal canal.

The bowels, in cases of gastric ulcer, are generally constipated, a symptom easily understood in the cases in which vomiting is a prominent symptom. Amenorrhœa is common. There is, however, little foundation for the idea that hemorrhage from the ulcer occurs vicariously in the place of menstruation, but the latter ceases, or is deficient, as in cases of anæmia produced by hemorrhages elsewhere, or from other causes.

The perforating ulcer occurs oftenest in young girls, and particularly in young maid-servants. Statistics show that females are more liable to ulcer, the proportion being as 2 to 1. Clinical observation fails to show any dependence on particular habits of diet, or other causes, nor has it any known relationship with other affections. It may be stated, however, that persons of feeble or impaired constitution are more liable to it than the robust.

The diagnosis of gastric ulcer may be made with much certainty, provided the diagnostic symptoms are present, namely, pain of a burning or gnawing character limited to a circumscribed space in the epigastrium, with tenderness also circumscribed, the pain felt directly after the ingestion of food, and especially after certain kinds of food, vomiting occurring during the process of stomach-digestion, and followed by relief, and, finally, gastrorrhagia or hæmatemesis. Analogous symptoms, it is true, may be present in cases of cancer of the stomach, but there are points of contrast involved in this differential diagnosis, which will be noticed presently in considering cancer. Moreover, the absence of a tumor appreciable through the abdominal walls goes far toward the exclusion of cancer. Chronic gastritis and ulcer have symptoms to some extent in common. But in chronic gastritis pain is less prominent, vomiting does not occur so frequently, and hemorrhage is wanting. In cases of gastralgia, the pain might suggest the idea of ulcer. But the pain in gastralgia is not aggravated, and, on the contrary, often relieved by the ingestion of food; tenderness over the epigastrium is not present, but the pain is often relieved by pressure; vomiting is an occasional symptom only, and hæmatemesis does not occur. In cases of merely functional disorder, pain, vomiting and hæmatemesis are all wanting. Hæmatemesis, it is to be borne in mind, is not alone evidence of ulcer. It occurs, irrespective of disease of the stomach, in certain cases of cirrhosis of the liver. It is the union of the several symptoms just named that renders the diagnosis complete. These diagnostic symptoms, however, are not united in all cases of

gastric ulcer. Hemorrhage is not invariably present; vomiting is not always a prominent symptom and may be wanting; pain and tenderness are not in all cases marked—the affection, in short, is sometimes latent, more or less difficulty or disturbance of digestion only being manifested. Under these circumstances, a positive diagnosis cannot be made. A strong suspicion of the existence of the affection may, in some cases, be reasonably entertained, when the symptoms do not warrant a positive diagnosis.

Gastric ulcer proves fatal in different modes. One of these is by perforation, diffuse peritonitis being induced by the escape of the contents of the stomach. In the great majority of cases, diffuse peritonitis caused by perforation of the stomach proves fatal. Recovery, however, is within the range of possibility. This accident would take place oftener than it does, were it not for the adhesion of the stomach to the adjacent organs as a result of circumscribed peritonitis. Perforation is most apt to occur when the ulcer is situated on the anterior surface of the stomach. The perforation generally takes place after the ingestion of a meal, or in the act of straining or sneezing, or in some sudden and forcible movement of the body. In some cases peritonitis, following perforation, occurs without having been preceded by any symptoms pointing to the existence of ulceration of the stomach. The following case is illustrative of the statement just made: A well-nourished woman of about 35 years of age had complained only of indigestion, when suddenly there occurred severe abdominal pain, followed by speedy collapse and death. Poisoning was suspected, and the autopsy was made by direction of the coroner. A round funnel-shaped ulcer of the size of a quarter of a dollar was found on the anterior wall of the stomach. Perforation had taken place and given rise to acute peritonitis. As has been stated, peritoneal adhesions having previously taken place, perforation may open a communication with the transverse colon. The evidence of this is stercoraceous vomiting.

Another mode in which it proves fatal is by hemorrhage. Life may be slowly destroyed by the continued escape of blood, or by repeated attacks of hemorrhage, or the loss of blood may be so rapid as to destroy life quickly. According to Brinton, death from hemorrhage occurs in the proportion of 1 to 20 cases.

Another mode in which it proves fatal, is by inanition. Death takes place by slow asthenia when the stomach is so intolerant of ingesta that aliment sufficient for the support of life is not retained. In other words, patients are gradually starved to death, provided life be not cut off by some other disease which the system may be rendered unable to resist in consequence of the debility incident to the stomach affection.

The duration is very variable. Death sometimes takes place from perforation or hemorrhage within a few weeks, or even a few days, after the time when the symptoms first denoted gastric trouble; or, as already stated, perforation and hemorrhage may occur when previous symptoms denoting gastric ulcer were wanting. But if these accidents do not prove the immediate cause of death, life is usually prolonged for many months, and it may be for many years. Brinton states that he has notes of one case in which probably a continuous open ulcer existed for 35 years, and of two cases in which the duration was 30 years, together with three or four of 20, four or five of 15, and several of 10, 7, 5, and 4 years' duration. It is not uncommon for the symptoms, from time to time, to subside, or to disappear, and subsequently to return. These remissions are probably due to healing of the ulcer which afterward again opens; in other words, relapses are apt to occur.

Gastric ulcer, although a serious affection, is by no means incurable. Brinton estimates that a cure takes place in about one-half of the cases which

occur. This estimate is based on the number of instances of cicatrized ulcer found in autopsical examinations.

The treatment of gastric ulcer embraces the following objects: *First*, and most important, securing for the stomach absolute rest; and *second*, the arrest of hemorrhage and the palliation of pain. Rest of the stomach is secured most effectually by resorting to rectal alimentation. This is advisable whenever symptoms render the diagnosis of gastric ulcer probable. It is now well established that, not only life, but complete satisfaction of the sense of hunger, and good nutrition, may be maintained indefinitely by the introduction of food into the rectum. Indeed, an increase of weight under an exclusively rectal diet has been observed. I can bear testimony to the prompt success of this method of treatment. The kinds of food to be employed and the practical rules to be observed are the same as in the treatment of acute gastritis (*vide* page 440). When the stomach tolerates food, that is, when pain and vomiting are no longer caused by ingesta *per orem*, the diet should consist, for a time, of milk, other articles being cautiously added or substituted. Considering the frequency of relapses, care to adjust the diet to the digestive power is advisable for a considerable period.

Hemorrhage is to be arrested by small pieces of ice swallowed, and by the application of cold to the epigastrium if the loss of blood be considerable. The fluid extract of ergot may be given *per enema*. Pain may require the use of opiates, the form being selected which is found on trial to be the least objectionable. They may be administered either by the rectum, or hypodermically. Pain and vomiting cease generally to be prominent symptoms if complete rest of the stomach be secured by rectal alimentation, so that the laudanum added to the nutritive injections suffices for all purposes.

It is doubtful whether any remedies exert a direct effect to promote cicatrization. The nitrate of silver and other remedies have been given with the expectation that they will exert a topical effect upon the ulcer. Clinical observation appears not to furnish evidence of their utility in this way. Cicatrization is promoted indirectly by remedies which arrest the peristaltic movements of the stomach and quiet the irritability of the organ, in other words, remedies which have reference to the first object of treatment, namely, securing rest.

Carcinoma of the Stomach.

Most of the tumors met with in other parts of the body may also occur in the wall of the stomach: fibroma, lipoma, sarcoma, myoma, gumma, tubercle, papilloma, adenoma, carcinoma. Of these, only carcinoma possesses clinical importance. For general considerations concerning the origin and structure of cancer, the reader is referred to Part First, page 45.

Of all organs in the body, the stomach is the most frequent seat of primary carcinoma.[1] Secondary cancer has also been met with in this organ, but it is very rare. The forms of carcinoma of the stomach are scirrhous (or fibrous), medullary (or encephaloid), colloid (or alveolar), and cylindrical-celled epithelioma. Of these, colloid is by far the least frequent. As the distinction between scirrhous and medullary cancer is based upon the difference in consistence, the former being hard and the latter soft, and as all degrees of

[1] Next in frequency comes the uterus. In d'Espine's (Geneva) collection of 889 cases of cancer, the stomach was affected 390 times, and the uterus 139 times; according to Virchow (Würzburg) 34.9 per cent. of all primary cancers are in the stomach, and 18½ per cent. in the uterus; of 587 cases of primary carcinoma compiled by Lange (Berlin), 210 were of the stomach and 147 of the uterus, vagina, or vulva. We may conclude with Brinton, that about one-third of all cancers are situated in the stomach.

combination and of transition exist between the two, statistics as to the frequency of the one or of the other are only of limited value. Hard cancer is more frequent than the very soft form. Combinations of hard and of soft cancer, and tumors of medium consistence are more frequent than either the very hard or the very soft varieties. Cylindrical-celled epithelioma is a common form of gastric carcinoma, according to some authors the most common. The most frequent seat of cancer is the pyloric region. The posterior surface and the lesser curvature are more frequently affected than the opposite regions. According to Brinton the cardia is affected in about ten per cent. of all cases.[1] Scirrhous cancer is characterized by the large amount of fibrous stroma and comparatively small development of cancerous alveoli. In the great majority of cases it is situated near the pylorus, where it sometimes appears as a partial or complete ring constricting the pyloric orifice. The cancerous alveoli may be so few and scattered that a very careful microscopical examination is required to distinguish scirrhous stenosis from purely fibrous stenosis of the pylorus (see page 448). Scirrhus may appear either infiltrated or in the form of distinct nodules. In medullary cancer the spaces filled with cancer cells predominate over the stroma which is usually richly infiltrated with round cells. This variety grows more rapidly and is more apt to be attended by metastases than the preceding. It forms a soft tumor, readily ulcerating, sometimes presenting fungous or villous excrescences upon its surface (so-called villous cancer). Soft cancer sometimes is unusually vascular and contains dilated bloodvessels (carcinoma hæmatodes); it rarely is stained with black pigment (melanoid carcinoma). Colloid cancer is rare. It may be combined in a nodular form with one of the other varieties, or it may appear as a diffuse thickening of the walls of the stomach, involving apparently its deeper coats. In the latter case, the peritoneum, as a rule, is extensively affected by the same process. This species of cancer is readily recognized by the clear, gelatinous substance found in its large alveoli. In cylindrical-celled epithelioma the alveolar structure conforms more closely than in the other varieties of cancer to the type of the normal gastric tubules. The cells contained in the alveoli, more particularly those which line the walls of the alveoli, are cylindrical in shape. In consistence this variety resembles medullary cancer.[2]

The opinion was formerly held that cancer of the stomach develops primarily in the submucous tissue and invades secondarily the other coats of the stomach. Since Waldeyer's view as to the epithelial origin of cancer-cells has been so widely accepted, it has been the teaching of many writers that carcinoma develops primarily in the mucous membrane. The process, as described by Waldeyer, is briefly as follows: A group of tubules (from 10 to 20) enlarge, lengthen and give off offshoots. They are filled with cells resembling usually the adelomorphous variety, but more granular and more deeply staining. The growth of the tubules with their branching offshoots is downward through the muscularis mucosæ. When the lax submucosa is reached, the progress is more rapid. Groups of cancer-cells now push their

[1] Lebert's statistics as to frequency are as follows: Pyloric region 51 per cent., lesser curvature 16, cardiac 9, anterior surface 3, posterior 4, anterior and posterior 4, greater curvature and fundus 7, diffuse infiltration 6 per cent.

[2] Cornil and Ranvier do not include epithelioma under the head of carcinoma, as they regard the former as an epithelial, and the latter as a connective-tissue, growth. Their description of cylindrical-celled epithelioma is also somewhat different from that of most writers. They describe the tumor as composed of branching tubules lined with cylindrical epithelium and presenting distinct lumina. Tumors of this type occur in the stomach, but they are generally considered to be adenomata, although Cornil and Ranvier expressly state that they differ from adenomata by the less regular arrangement and shape of the tubules.—*Manual of Pathological Histology*, American translation, pp. 154 and 476, Philadelphia, 1880.

way in all directions, chiefly in the lymphatic vessels and spaces. Cancerous masses penetrate between the bundles of smooth muscular tissue and often extend to the subserous and serous coats. The growth may be so much more extensive in the submucous coat that the tumor appears to originate there, but, according to Waldeyer, careful microscopical examination will always disclose some band of connection with the tubules of the mucous membrane. The growth, however, may from the first involve chiefly the mucous coat, and in any case this is, as a rule, sooner or later extensively invaded.

It has already been mentioned that cancer of the stomach may appear in a diffuse or in a nodular form, also as a ring, especially about the pylorus. Ulceration is a frequent occurrence. This change is the rule with medullary and cylindrical epithelial, and is not infrequent with scirrhous, cancer. There is less tendency in colloid cancer than in the other varieties to ulceration. Ulceration is not always to be regarded as an unfavorable occurrence. Especially the soft cancers may be much reduced in size by this destructive process. This reduction may relieve an existing stenosis of the pyloric or cardiac orifice. The shape of the ulcer, particularly when the cancer is medullary, has been often compared to that of a crater—a peripheral wall of cancerous tissue surrounding a central loss of substance. Exceptionally, in cases of scirrhus, the ulcer may bear much resemblance to simple or round ulcer with indurated walls, and this fact is to be considered in weighing the statements of those who report numerous cases of cancer developing from round ulcer.[1] Scirrhous cancer often contains considerable cicatricial tissue, but there is no positive reason to believe that it ever heals. The muscular coat in the neighborhood of cancerous growths is almost always hypertrophied. If the tumor produce stenosis of the pylorus, the rest of the organ is dilated; if the cardiac orifice be constricted, the stomach is reduced in size. Chronic gastritis is a frequent attendant upon cancer. Chronic circumscribed peritonitis with the formation of adhesions is common in the neighborhood of the cancer. The wall of the stomach may be perforated by cancerous ulceration leading to invasion of the surrounding organs, to perforative peritonitis or to fistulous communications. Peritonitis from perforation is less frequent with cancerous than with simple ulcer.[2] The erosion of large vessels is also less frequent in cancer than in ulcer. General peritonitis may occur without perforation.

Carcinoma may extend by continuous growth into surrounding parts. It may also lead to metastases or secondary deposits. The lymphatic glands near the stomach, also the liver, the peritoneum, and the lungs are affected in frequency in the order named. Secondary deposits in the liver are those most frequently detected during life.[3] Metastases occur most frequently through the lymph-vessels, but may also occur through the blood-current. An actual growth of carcinoma into the rootlets and main trunk of the portal vein has been observed. The secondary deposits generally conform in structure with the primary growth. It is worthy of note that large and numerous secondary deposits may attend small and insignificant tumors of the stomach, which, during life, may have produced no symptoms, and after death may be overlooked on superficial examination. The blood in cases of cancer of stomach may present the same alterations as in pernicious anæmia.

The symptoms which make up the clinical history of this affection are as

[1] Thus Lebert states that in 9 per cent. of the cases, cancer develops from simple ulcer. Deutsches Archiv für klinische Medicin, Bd. 19, p. 545, 1877.

[2] Perforation into the peritoneal cavity occurs according to Brinton in a little over 4 per cent. of the cases, according to Lange in a little over 5 per cent.

[3] According to Brinton and Dittrich, the liver contains cancer in about 25 per cent. of all cases of cancer of the stomach; according to Lebert in about 40 per cent.; according to Lange in 31 per cent.

follows: Impaired appetite, or anorexia, is generally more or less marked, but in some cases the desire for food is preserved. Pain may be more or less prominent, and the character of the pain may be lancinating. In many cases, however, the lancinating pain which attends cancer in other situations is either slight or wanting. A circumscribed gnawing pain may be incident to the ulcer occurring as secondary to the cancer. Tenderness over the epigastrium may, or may not, exist. Vomiting is a frequent symptom, but it occurs less frequently than in cases of simple ulcer, and at a later period after taking food. The vomiting, if the cancer be at the pylorus, may be chiefly due to obstruction at this orifice and consequent accumulation of gastric contents. The cryptogamic plants, sarcinæ and torulæ, may be found in the vomited matters when these have undergone fermentation within the stomach. Blood is not infrequently found in the vomited matters, generally in small quantity, and having the coffee-grounds appearance. With these symptoms referable to the stomach are associated progressive loss of weight and strength, anæmia, usually constipation, but occasionally diarrhœa, and in some cases jaundice. The last-named symptom points to the probable occurrence of secondary cancer affecting the liver.

Certain general considerations pertaining to the causation of tumors, have been alluded to in Part First, page 43. As to the primary cause of cancer, we are without any positive information. It is probable that the cachexia is secondary to the development of the cancer. The cachexia may be explained partly by certain facts pertaining to cancer in general, and in part by the local injury which the growth inflicts upon an organ of such vital importance as the stomach. The general considerations are, the rapid growth of the tumor, its withdrawal in a short time from the circulation of a large quantity of nutriment employed only for its own noxious growth and for no useful purpose, its destruction of healthy and useful tissues, the production of metastases which for their nutrition and growth, from their number and size, make even greater claims upon the organism than the primary tumor, and often the occurrence of exhausting hemorrhages. The local effects of cancer of the stomach—loss of appetite, pain, vomiting, mechanical disturbance of the digestive functions, and chemical alterations in the gastric fluids—are often in themselves sufficient to explain an extreme degree of cachexia. While these general and local effects suffice to explain the cachexia in most cases of carcinoma of the stomach, there are a small number of cases in which they do not seem to be operative, and in which it seems necessary to assume the entrance into the blood of some virus produced in the tumor.

The liability to cancer of the stomach is slight before the age of forty. Three-fourths of all cases occur between forty and seventy years of age; the largest number between fifty and sixty. Men are somewhat more frequently affected than women, but the disproportion is not great.[1] Heredity is a well-established element in the causation of cancer of stomach, as of cancer elsewhere.

Cancer of the stomach is to be discriminated from merely functional disorder, or dyspepsia, chronic gastritis and gastric ulcer. In merely functional disorder, pain and vomiting are symptoms rarely as prominent as they are generally in cancer. The ailments in dyspepsia are seldom so protracted; they do not lead to the same amount of emaciation, feebleness, and pallor; hæmatemesis is wanting. The same is true of chronic gastritis. Persistent disturbance

[1] The older statistics (d'Espine, Louis, Valleix, Brinton) showed a considerable preponderance of cancer of the stomach in males. The more recent and extensive statistics of Wilson Fox, Lebert, and Lange do not show any essential difference in causation as regards sex.

of digestion, especially if accompanied by pain and vomiting, leading to considerable loss in weight, diminution of strength, and anæmia, in a person between forty and seventy, should always excite suspicion of cancer. Cases of gastralgia lack all the diagnostic features of cancer except pain. Gastric ulcer is liable to be confounded with cancer, and, in view of the great difference as regards prognosis, it is desirable to discriminate between these affections. They present certain points in contrast as regards the symptoms. In cancer the appetite is more impaired than in ulcer. Vomiting is more uniformly present in ulcer; it occurs earlier after the ingestion of food, and, in general, is evidently due to the irritation caused by the presence of food. In cancer it is present in only a certain proportion of cases; it does not follow so soon after taking food, and is frequently due to the mechanical distension of the stomach owing to the pyloric obstruction. Hemorrhage is more constant and more profuse in ulcer. If the patient be a young girl, the chances are much in favor of ulcer. The duration of the local symptoms is of importance in this differential diagnosis; if the symptoms have existed for a long period, the chances are in favor of ulcer rather than cancer. Age is to be considered in the diagnosis, cancer occurring rarely before forty. Enlargement of lymphatic glands above the clavicles accompanies cancer in some cases, and has some weight in the diagnosis.

Considerable importance has been attached to the complexion which has been supposed to denote the cancerous cachexia, namely, pallor with a faint tint of yellow or green, the conjunctiva remaining unaffected. It has been called a waxy complexion. This is sometimes well marked in cases of cancer, but it is by no means always present, nor is it pathognomonic when marked. If members of the family have had cancer, this fact is entitled to some weight in the diagnosis. So, also, is the co-existence of cancer in some other situation.

In some cases of cancer there are few or no symptoms denoting any serious affection up to a short time before death. Like gastric ulcer, it is sometimes remarkably latent, the patient appearing to suffer only from moderate or slight dyspeptic ailments, the appetite remaining unimpaired, the strength not failing, and the aspect indicating health. Several cases illustrative of this fact have fallen under my observation. In these latent cases, and also when the differential diagnosis relates to ulcer and chronic gastritis, great importance belongs to the discovery, or otherwise, of an abdominal tumor in the site of the stomach. Exclusive of the cases in which the cardiac orifice is the seat of the cancer, a tumor is discoverable by physical examination in the majority of cases. According to Brinton, it exists in 80 per cent. of all cases of cancer. The tumor is situated generally between the false ribs and the umbilicus, a little to the right of the median line. It may be movable or fixed; much more frequently the latter. If movable, it will be likely to change its situation accordingly as the stomach is distended or empty. The tumor varies in size from a pigeon's egg to the size of the closed hand. The weight of the tumor may cause it to fall below the epigastrium, and it may descend nearly to the symphysis pubis. It is usually resisting, and the surface irregular or nodulated.

The presence of a tumor, if ascertained to be seated in the stomach, renders the diagnosis almost positive. But it is not always easy to decide positively that the tumor is seated in the stomach. A cancerous tumor may simulate aneurism of the abdominal aorta. The characters of an aneurismal tumor are expansile pulsation, thrill, and murmur. A cancerous tumor may present, more or less marked, the same characters. It may present not only a single, but a double, murmur. How are the two to be distinguished from each other? An aneurismal tumor has usually a smooth outline, and may be diminished by pressure; the pulsation is felt laterally as well as on its anterior surface;

by a change of position of the patient, as placing him on his hands and knees, the pulsation is not materially affected, whereas if the tumor be not aneurismal, its pressure on the artery is taken off and the pulsation may be found to cease. But aneurismal tumors do not always pulsate, and both thrill and murmur may be wanting. Under these circumstances, in this differential diagnosis, reliance must be had upon the diagnostic points relating to the history and symptoms. These are, of course, always to be carefully considered. Other tumors, from their situation, are liable to be confounded with cancer of the stomach, namely, tumors connected with the left lobe of the liver and with the pancreas, fecal tumors, etc. The distinctive characters of these will be considered in other connections. A point of distinction, as contrasted with tumors seated in the liver, is, that the latter are depressed in an act of deep inspiration, whereas, the descent of the diaphragm does not affect the situation if the tumor be seated in the stomach. Moreover, percussion over an enlargement of the left lobe of the liver gives flatness, whereas, a tympanitic resonance is elicited usually over a gastric tumor. There is a liability to mistake the normal pancreas for a tumor, owing to different degrees of distension of the stomach; the tumor may be felt at some times and not at other times.

Cancerous affection of the cardiac orifice, leading to stenosis, gives rise to symptoms quite different from those which accompany cancer of the stomach elsewhere situated. Food accumulates in the lower part of the œsophagus, and is regurgitated directly after deglutition. The obstruction, if considerable, interferes with vomiting as well as the ingestion of food. The food is regurgitated without change, and is devoid of the taste and odor of the gastric fluids. The patient is unable to take solid food, and is compelled to take liquids slowly and in small mouthfuls. In these cases, a tumor is not discoverable. The symptoms are the same as in cases of stricture at the lower portion of the œsophagus from other than cancerous disease, and the differential diagnosis cannot always be made with positiveness. Spasmodic stricture of the œsophagus may simulate contraction from either cancer or some other organic affection. The passage of a probang into the stomach will enable the practitioner to exclude the latter. Adhering to the probang or sound passed into the cardiac orifice, may be cancerous particles which establish the diagnosis.

A microscopical examination of the matters vomited, in cases of suspected cancer, may lead to the discovery of cancer elements. This test is only available at an advanced period of the disease, and then only in a very small proportion of cases.

The prognosis in cases of cancer of the stomach is as unfavorable as possible. If a cure be within the range of possibility, the probabilities are so vastly against it that we are not warranted in entertaining the least expectation of such a result in any individual case. A fatal termination is merely a question of time. Statistics show the average duration to be about a year from the date of the first gastric symptoms. The maximum duration is about three years, and the shortest period is a month. Death occurs by slow asthenia, except in rare instances from profuse hemorrhage or from perforation of the stomach. Œdema of the lower limbs and ascites occur in some cases. The former may be caused by thrombosis of the femoral veins; the latter may be produced by pressure upon the portal vein of a cancerous nodule connected with the liver, or the formation of a thrombus within the vein.

The treatment has reference only to the prolongation of life and the palliation of symptoms. A diet, bland and nutritious, consisting of the articles of food which experimental trials, in each case, show to be best borne, taken in quantities and at intervals to be determined also by trial; remedies to relieve

pain and quiet the irritability of the stomach; avoidance of cathartics and any measures which impair the vital powers,—these are the points to be kept in view in the management of this distressing and hopeless affection. Nourishment by means of rectal alimentation, in cancer of the stomach involving pyloric obstruction, prevents pain and vomiting resulting from the accumulation of ingesta and the chemical changes incidental thereto. It may be resorted to as supplementary to a limited quantity of food taken into the stomach. Withdrawal, from time to time, of the accumulated contents of the stomach, by means of the pump or siphon, in the manner to be described in connection with dilatation of the stomach, has been found to afford marked relief. In cases of cancer causing obstruction of the cardiac orifice, the sensation of hunger is removed and life prolonged by resorting to rectal alimentation. These desirable results were manifested in a case under my observation. Buttermilk is sometimes better tolerated in cases of cancer than any other article of diet. Cases have been reported in which the cundurango appeared to have a beneficial effect. Chian turpentine has been lately recommended by Clay and others in all forms of cancer.

Dilatation of the Stomach—Gastrectasia.

Since Kussmaul's publication[1] in 1869 concerning the treatment of dilatation of the stomach by means of the stomach-pump, increased attention has been devoted to the etiology, symptomatology, and treatment of this affection. As the normal dimensions of the stomach vary in different individuals within wide limits, it is manifestly impossible to give an exact anatomical definition of this disease. While well-marked examples cannot be mistaken in post-mortem examination, it is often impossible to recognize the lesser grades of this disease. During life certain characteristic disturbances of the physiological functions of the stomach are of great importance in reaching a diagnosis, sometimes of greater importance than the anatomical investigation.

When dilatation of the stomach is excessive, the organ may occupy the greater part of the abdominal cavity, and may even descend into the pelvis. In less extreme cases the lowest part of the stomach lies somewhere between the umbilicus and symphysis pubis. By increased weight the whole organ is generally dragged downward, especially the pyloric portion, when it is movable, so that the position of the stomach is more nearly vertical than normal. When dilatation is due to stenosis of the pylorus, the muscular coat is almost invariably hypertrophied; in the so-called atonic dilatation, to be described presently, the muscularis may be of normal or of reduced thickness. In one case fatty and colloid degeneration of the muscular fibres was found (Kussmaul and Maier). The mucous membrane is sometimes thickened and sometimes thinned. It is readily understood that neighboring organs may be more or less displaced by a widely distended stomach.

It is important to know that the stomach may be situated abnormally low in the abdomen without being dilated. Thus if, during life, the lower part of the stomach be found a hand's breadth below the umbilicus, it does not necessarily follow that it is dilated. The so-called vertical position (situs verticalis) of the stomach is a not infrequent malposition which simulates dilatation. In this condition the pyloric orifice is lower than normal, and may be in nearly a vertical line with the cardia. The position may be a preservation of the fœtal state, or it may be acquired as a result of pressure (in women especially by tight lacing). As pointed out by Kussmaul, the greater curvature may occupy an abnormally low position in consequence of the so-called

[1] Kussmaul, Deutsches Archiv f. klin. Med., Bd. 6, p. 455.

looped shape (Schlingen-form) of the stomach. In this state the pylorus is nearer the cardia than normal, and the lesser curvature is abnormally sharp.

Kussmaul distinguishes two forms of dilatation of the stomach, the hypertrophic and the atonic.[1] In the former the muscular coat is hypertrophied, and the cause, in the great majority of cases, is obstruction at or near the pyloric orifice. In the atonic form the muscular coat is relaxed, and after death is found but little, if at all, hypertrophied, and it may be atrophied. Hypertrophic dilatation he compares, not inappropriately, to excentric hypertrophy of the heart.

The causes of dilatation relate, in the first place, to mechanical obstacles to the passage of the contents of the stomach into the intestine. The obstacles may be various. They may be seated in the upper part of the duodenum as well as in the stomach. The most frequent and important are cancer and the cicatrices resulting from old ulcers. Other causes of organic stenosis of the pylorus are, tumors of neighboring organs, causing external pressure, particularly cancer of the liver and of the pancreas, the contraction of cicatricial tissue resulting from perigastritis and the inflammation of connective tissue near the stomach, hypertrophic stenosis (see page 448), the pressure upon the duodenum of a wandering right kidney, and, as rarities, fibroma, lipoma, glandular and cystic polypi of the pylorus. A very rare condition is congenital stenosis of the pylorus.[2] Dilatation has been referred to traction upon the stomach produced by large scrotal hernias. According to Kussmaul it may be referable to spastic stenosis of the pylorus. The sphincter pylori may be thrown into spasmodic contraction by painful erosions, ulcers, and inflammations in its neighborhood. Destruction of a part of the muscular coat near the pylorus is evidently an obstacle to the propulsion of food through this orifice, and so may lead to dilatation. In this way ulcers and cancers which destroy the muscularis may produce dilatation, even when they do not obstruct the lumen of the stomach. It has already been mentioned that cirrhosis of the stomach, which is usually attended by contraction, may exceptionally be accompanied by dilatation. Causes which may lead to the production of atonic dilatation, according to Kussmaul, are the following: 1. Weakness of the muscular tone of the stomach from imperfect nutrition in cases of anæmia, chlorosis, exhausting acute and chronic diseases, amyloid degeneration of the gastric arteries. 2. Weakness and paralysis of the motor nerves of the stomach, for example, as a result of destruction of the terminal branches of the vagus by an ulcer. 3. Peristaltic torpor, that is, diminished irritability of the peristaltic nerves or centres. 4. Inhibition of the peristaltic activity of the stomach by reflex action. Predisposing causes of dilatation are chronic catarrhal gastritis, a vertical position of the stomach, and the presence of adhesions to surrounding parts. Individuals of sedentary habits, who eat and drink a great deal, are liable to develop dilatation. The polyphagia which attends diabetes thus becomes a cause of dilatation. The dilatation which results from organic stenosis of the pylorus, reaches a more extreme degree than that from other causes, and is accompanied by a greater hypertrophy of the muscular tunic.

Vomiting occurs almost without exception when dilatation is due to pyloric obstruction; in other cases it is a frequent, but not a constant, symptom. The characteristic features, as regards this symptom, are the occurrence of the vomiting after periods varying from a day to several days, the large quantity of the matters vomited, amounting sometimes to several quarts, and

[1] Kussmaul, Die peristaltische Unruhe des Magens. Volkmann's Sammlung klinischer Vorträge. Leipzig, 1880.

[2] Landerer, Ueber angeborne Stenose des Pylorus. Tübingen, 1879.

the presence of undigested aliment which had been taken the previous day or several days previously. The matters vomited are almost invariably acid, and frequently they are in a condition of fermentation as indicated by a froth containing gas, sometimes inflammable, in the upper layers. Sarcinæ, the yeast fungus or torula cerevisiæ, and crystals of fatty acids are often found. Acetic, lactic, butyric, and other organic acids are usually present. Van den Velden has discovered an interesting fact in regard to the presence of hydrochloric acid, the normal acid of the gastric juice. He failed to find this acid in any case of dilatation due to cancer of the stomach. In dilatation from other causes, it was often, but not invariably, present. According to this author, if hydrochloric acid be detected in the contents of the stomach, obtained by means of the stomach-pump, obstruction from cancer may be excluded. If this acid be persistently absent, no positive conclusions can be drawn.[1] Bile is not often found in the matters vomited or withdrawn by the stomach-pump, if the dilatation be due to stenosis of the pyloric orifice.

The feature pertaining to the contents of the stomach, which appears to be most diagnostic of dilatation, is their retention for a day or for several days within this organ. This may be ascertained by washing out the stomach in the morning before food has been taken. In healthy persons the stomach does not contain in the morning any of the ingesta of the preceding day; the ingesta may remain overnight in cases of temporary indigestion, but, if they are habitually present in the morning, it is certain that the power of the stomach to propel its contents into the duodenum is wanting. This condition leads to dilatation. It is called by Rosenbach insufficiency of the stomach, and, of course, it may exist for a time before dilatation ensues.

Dilatation of the stomach may occasion an abnormal prominence of the abdomen, especially marked at the epigastrium, and extending more or less below the umbilicus. The projecting tumor yields at the upper part a tympanitic resonance on percussion having the characteristic gastric quality of sound. At the lower portion, if the stomach contain ingesta, there is flatness on percussion, and the relative situation of the flatness and tympanitic resonance changes when the position of the patient is changed from the vertical to the recumbent. In succussion a splashing sound is produced analogous to that in pneumo-hydrothorax. With the ear or stethoscope placed over the stomach, metallic tinkling may be heard when the patient swallows liquid. Kussmaul describes a sizzling sound produced by bubbles of gas generated by fermentation. These auscultatory signs, however, are not distinctive of dilatation; they may be caused by the presence of air and liquid in a stomach more or less distended, but not dilated. If the abdominal walls be thin, the form of the stomach may be apparent, and its undulatory movements visible. According to Kussmaul, these peristaltic undulations are characterized by their intensity, their long duration, and by coming on speedily after meals. They may give rise to disagreeable sensations, whereas, in health, persons are unconscious of the peristalsis of the stomach. The enlargement of the stomach varies at different times according to the variations in the quantity of ingesta and gas. A sense of fluctuation may be perceived by the touch when the stomach contains considerable liquid.

With the object of ascertaining the amount of dilatation by the eye and by percussion, the method of generating gas within the stomach, as first proposed by Frerichs, may be resorted to. Kussmaul states that the quantity of effervescing powder required to bring out distinctly the contour of the organ

[1] Van den Velden employed, among other tests for hydrochloric acid, methyl aniline violet, which becomes a bright blue if a mineral acid be added, but remains unchanged by organic acids (Deutsches Archiv klin. Med., Bd. 23, p. 373, 1879).

varies in different persons according to its capacity, the tension of the walls of both the stomach and the abdomen, the reflex susceptibility to vomiting, etc. From 20 to 30 grains of bicarbonate of soda and from 15 to 20 grains of tartaric acid may be at first introduced. The soda is to be given in a little lukewarm water, and followed by the acid. Some persons with relaxed, dilated stomachs require two or two and a half drachms of soda and a corresponding quantity of acid.[1] The amount of dilatation may also be demonstrated by means of a stomach-sound, the length which is introduced being ascertained, and the extremity can sometimes be felt by the hand applied over the abdomen.

It is important to know that a person may be found to have an unusually capacious stomach, but if it do its work well, that is, if it be sufficient in the sense in which this term is used by Rosenbach, and is empty in the morning, there is no propriety in considering the large size of the organ as a morbid condition, any more than a similar condition of the bladder. On the other hand, the signs may not denote much enlargement; but if the organ be insufficient, its muscular power being inadequate to propel the contents during the night into the intestine, either dilatation exists or a condition leading thereto. Since attention has been directed to dilatation of the stomach more than heretofore, it has probably not infrequently been diagnosticated on insufficient grounds. No organ in the body varies in volume more widely within the range of health than the stomach, and an unusually large volume is not to be considered as dilatation unless the symptoms denote habitual undue detention of the ingesta.

In cases of dilatation the quantity of urine is often diminished and its reaction alkaline. The bowels are constipated. The body wastes from innutrition. The symptoms of cancer of the stomach, when the pylorus is obstructed, are referable, in a great part, to the dilatation which ensues.

Paracentesis has been practised in a case of enormously dilated stomach, under the belief that the affection was hydro-peritoneum. Physical examination of the abdomen, in addition to the symptoms characteristic of dilatation, should enable the practitioner to avoid this error. In hydro-peritoneum, the enlargement is not uniform, but is greatest at the lower part of the abdomen, the reverse being true of dilatation of the stomach. In hydro-peritoneum, the enlargement is proportionate anteriorly and laterally; in dilatation of the stomach, the anterior projection is greater than the lateral. In hydro-peritoneum, flatness on percussion exists at the lower part of the abdomen; in dilatation of the stomach, intestinal tympanitic resonance will be likely to be found below the space which yields flatness, namely, in the hypogastric and iliac regions. The variation in the enlargement, and its disappearance after complete vomiting or the use of the stomach-pump, suffice for the diagnosis.

If not dependent on pyloric stenosis, a considerable degree of dilatation may not give rise to notable inconvenience; but if the dilatation be great, nutrition suffers in consequence of the non-absorption of the accumulated ingesta. Rupture may occur if the walls be attenuated. A fatal termination, however, irrespective of carcinoma or other diseases which occasion obstruction, is rare.

Regulation of the ingesta as regards quantity and quality, together with tonic remedies, constitutes appropriate treatment. Indigestible food and articles

[1] Ebstein has described under the name insufficiency of the pyloric valve (incontinentia pylori) a condition in which the gas thus generated is not retained in the stomach, but rapidly escapes into the intestine through the pyloric orifice (*vide* Ueber die Nichtschlussfähigkeit des Pylorus, Sammlung klinischer Vorträge von Volkmann, No. 155, 1878).

which, from decomposition, develop gas in abundance, should be interdicted. The diet should consist of meat, milk, soups, and eggs. Saccharine and amylaceous articles are to be avoided in consequence of their tendency to fermentation. Strychnia or nux vomica may be given with a view to increase the muscular tone of the stomach. Artificial digestion may, in a measure, be effected by pepsin and hydrochloric acid. Food artificially digested before it is ingested (peptones) is appropriate. Kussmaul recommends the withdrawal of the contents of the stomach, by means of the stomach-pump, whenever there is evidence of undue detention, and claims that a cure may by this method of treatment be sometimes effected. The advantages of this method, as a means of obtaining relief, are obvious; but it is preferable, if practicable, to adjust the diet so that undue detention will not take place. Inasmuch, however, as this is not always practicable, if there be pyloric stenosis, the use of the stomach-pump is a valuable resource. When the obstruction is so great that the system fails to receive sufficient alimentary supplies by the stomach, supplementary rectal alimentation becomes an important measure of treatment. In some cases it may be advisable to nourish, for a time, wholly by the rectum. Giving the stomach nothing to do in the way of digestion, is preferable to the introduction into it of ingesta to be withdrawn. There is, moreover, risk of injury from the suction force of the stomach-pump. Portions of the mucous membrane of considerable size have been repeatedly torn away and withdrawn by the pump. As yet, however, no instance of serious injury from this cause has been reported. The siphon may be used instead of the pump, and is unattended by risk of injury, but it is ineffectual for the removal of solid contents. Kussmaul recommends washing out the stomach every alternate morning before taking food. Patients may learn to wash out their own stomachs.[1]

Degeneration of the Gastric Tubules.

Together with the liver, kidneys, and heart, the stomach is a frequent seat of *parenchymatous degeneration* or *cloudy swelling* (see Part First, p. 54). In this condition the mucous membrane is somewhat swollen, and may be either congested or pale. The microscope shows the glandular cells to be swollen and filled with albuminous granules which, at least in great part, dissolve in acetic acid. The contours of the cells may be so obscured that the tubules seem to be filled with a granular mass. This change, when of much intensity, frequently leads to *fatty degeneration*. The cells now contain fatty molecules which refract the light more than the albuminous granules, and are not soluble in acetic acid. In extreme degrees of this degeneration, such as may occur in phosphorus poisoning, the cells are more or less disintegrated and their places occupied by a fatty and albuminous detritus. The most frequent and important causes of parenchymatous degeneration are the febrile and infectious diseases, of which may be especially mentioned typhus and typhoid fevers, smallpox, septicæmia, puerperal fever, yellow fever. Phosphorus poisoning has been mentioned as a cause of the more extreme grades leading to fatty degeneration. Poisoning by arsenic, mercury, or the mineral acids, is said to produce similar changes. It cannot be doubted that these alterations in the peptic cells impair the secretion of the gastric juice. It is reasonable to refer to them many of the disturbances in digestion which characterize the conditions named. Parenchymatous degeneration in the stomach, as elsewhere, is a condition from which recovery readily takes place when its causes are removed.

While treating of the different forms of gastritis, reference was made to

[1] For further details *vide* article by Leube in Ziemssen's Cyclopædia, vol. vii.

changes of the tubules, mostly of a degenerative character, which occur in inflammatory states. Parenchymatous and fatty degenerations and atrophy of the tubules were the most important of these alterations. An interesting comparison is often drawn between the changes in the gastric mucous membrane in chronic inflammation, and those in the kidney in chronic diffuse nephritis. In both there are increase of the interstitial tissue, fatty degeneration of the glandular epithelium in certain places, atrophy of the tubules, constriction of the tubules at certain points and cystic dilatation at others.

There is reason to believe that degenerative changes in the gastric mucous membrane occur independently of chronic inflammation and of the various causes of parenchymatous degeneration. *Atrophy of the stomach, atrophy or degeneration of the gastric mucous membrane or of the gastric tubules,* are names which have been employed to designate these changes. Alterations in the gastric glands have been studied especially by Handfield Jones, Wilson Fox, Habershon, and Fenwick. It is generally recognized that atrophic changes occur in the mucous membrane of the stomach, as in other organs, in chronic wasting diseases and in old age. But it is maintained by Fenwick and others that atrophy of the stomach occurs also as a primary morbid condition attended by grave symptoms; in other words, that it constitutes a disease by itself. So long ago as 1860, in a published lecture on anæmia, I ventured to predicate degeneration of the gastric tubules on the anatomical basis of certain cases now included under the name pernicious anæmia (see page 392 *et seq.*).[1] In the third edition of this work (1868) I predicted that future investigations would disclose important facts pertaining to morbid conditions seated in the gastric tubules. In an essay published in 1871[2] I endeavored to still further substantiate these views. My conclusions were based partly on deduction, and partly on the anatomical studies of Jones, Fox and Fenwick. My object was to show, from a clinical point of view, *first*, the existence of a well-defined class of cases characterized by anorexia, impaired digestion, progressive debility, anæmia, and death from inanition; and, *second*, in view of these clinical characteristics, together with the absence of adequate lesions elsewhere, the probability that the essential disease is seated in the secretory glands of the alimentary canal. It is gratifying to be able to add, in the present edition, some contributions to our knowledge of this still obscure subject. Fenwick, in a lecture on atrophy of the stomach, in 1877,[3] published four cases with autopsies showing atrophy of the gastric tubules without thickening of the walls and without diminution of the lumen of the stomach. The symptoms resembled closely those which have been described in the article on pernicious anæmia. Quincke, in an essay on pernicious anæmia,[4] mentions a case in which the gastric symptoms were even more marked than is usual in pernicious anæmia, and in which, after death, the gastric mucous membrane was found to be thin and pale, the glands being few and far apart. He suggests that the atrophy of the gastric mucous membrane may have been the starting-point of the disease. Brabazon, in 1878,[5] reported a case of general atrophy of the stomach, with absence of organic disease. The symptoms during life were anorexia and extreme anæmia. The walls of the stomach were found to be atrophied, but unfortunately no microscopical examination was made. In 1879 Nothnagel[6] published a case of cirrhotic con-

traction of the stomach, attended by disappearance of the gastric glands in all parts except the pyloric region. The microscopic examination was made by W. Müller. The clinical history of this case was in all respects that of pernicious anæmia, and this was the diagnosis during life. Nothnagel does not hesitate to refer these symptoms to the atrophy of the gastric tubules. As he remarks, atrophy of the gastric glands appears under two conditions, the one with, and the other without, thickening of the walls of the stomach. The former condition corresponds to cirrhosis of the stomach, the latter to simple atrophy. It is the latter form to which Fenwick has called especial attention. In some of the reported cases, an increase of the interstitial tissue of the mucous membrane has been observed, but whether it is primary or secondary is uncertain. Even if the interstitial change prove to be primary, there is no propriety, as Nothnagel justly says, in considering the process as an ordinary chronic catarrhal gastritis.

The symptoms which have been observed with atrophy of the gastric tubules are those of severe anæmia. The digestive symptoms are loss of appetite, vomiting usually but not always, distress after eating, eructations. All of these symptoms are frequently observed in cases of pernicious anæmia. It would be well, as Nothnagel suggests, to pay especial attention to the condition of the stomach in death from pernicious anæmia. The pathological conditions are probably not the same in all cases of this grave form of anæmia. That a certain proportion of the cases are referable to atrophy of the gastric tubules may reasonably be inferred from cases already published. From a clinical standpoint, it is important to take cognizance also of atrophy of the glands of the stomach as a secondary change in various affections of this organ, especially in chronic inflammation and in cancer. It is to be expected that in the future greater attention will be directed to the condition of these important glands in disease, and that valuable contributions will thereby be made to our knowledge of this recently opened field of research.

Waxy degeneration of the walls of the stomach is not a very infrequent condition in cases in which this degeneration is widely extended. As a rule, the metamorphosis is more marked in the small and large intestine than in the stomach. All the coats of the stomach may be involved, but generally the change is greatest in the muscularis mucosæ and the mucous membrane. Here, as elsewhere, the waxy material appears first in the walls of the small arteries and about the capillaries, and it may be confined to these structures. The change may, however, extend to the surrounding tissues. In the majority of cases, the epithelial cells of the tubules do not seem to have undergone the waxy metamorphosis, but that they may become waxy has been proven by the observations of Wilson Fox, Dmietrowski, and Kyber. According to Kyber, amyloid degeneration of the stomach is generally accompanied by chronic inflammatory changes and pigmentation. An observation by Meckel and one by Kyber[1] render it probable that extensive amyloid degeneration may so impair the nutrition of the gastric mucous membrane as to favor the development of round ulcer. Although, according to Kühne, the amyloid material outside of the body is extremely resistant to the action of the gastric juice (see p. 57), it would appear from the studies of Kyber that this substance in the living body may be digested by the gastric juice. Amyloid degeneration is generally an accompaniment of severe wasting disease (p. 58). That the functions of the stomach are impaired by this metamorphosis is in the highest degree probable, but we are without positive information on this point.

CHAPTER IV.

STRUCTURAL AFFECTIONS OF THE INTESTINE. INTESTINAL OBSTRUCTION.

Intestinal Ulcers—Duodenal Ulcer—Embolism of the Superior Mesenteric Artery—Carcinoma of the Intestines—Waxy Degeneration of the Intestines—Structural Lesions causing Intestinal Obstruction—Intussusception—Strangulated Hernia within the Abdomen—Rotation or twisting of Intestine—Compression and Stricture of the Intestine—Obstruction from Impaction of Feces, Enterolithes, and Foreign Bodies—Functional Obstruction.

Intestinal Ulcers.

IN this connection it is convenient to enumerate the different varieties of intestinal ulcers, although many of the forms are considered in connection with diseases in which they occur. The important forms of intestinal ulcers are the following: simple inflammatory (including follicular), digestive, dysenteric, typhoid, tuberculous, and syphilitic. Certain rare varieties, as the embolic, the amyloid, the corrosive (from swallowing corrosive poisons), the variolous, and the mycotic (especially in malignant pustule), will receive no further attention.

Ulcers may occupy any part of the intestinal tract. In general, it may be said that their favorite seats are the ileum, the cæcum, the sigmoid flexure, and the rectum. Simple inflammatory ulcers, also called catarrhal, have been treated of in connection with dysentery and with enteritis. They include follicular and non-follicular forms. Ulcers produced by pressure of impacted feces are sometimes called stercoral. Similar ulcers may be caused by foreign bodies. These ulcers from pressure are most frequent in the cæcum, vermiform appendix, and sigmoid flexure. They have been considered in connection with typhlitis (see page 427 *et seq.*). Digestive ulcers occur only in the upper part of the intestine. They are of the same nature as digestive or simple gastric ulcer, and will be considered in the next article under the head of duodenal ulcer. Dysenteric ulcers have already been described. The so-called uræmic ulcers, which occur in Bright's disease, and which are sometimes attributed to the irritation of carbonate of ammonia produced from urea in the intestinal tract, are in some cases the result of a dysenteric process. Dickinson has observed small ulcers in the lower part of the ileum in combination with small contracted kidney. Typhoid ulcers will be described subsequently in connection with typhoid fever.

Tuberculous intestinal ulcers are very frequently present in cases of pulmonary tuberculosis. They very rarely, if ever, occur independently of tuberculous processes in the lungs. The hypothesis that the intestinal ulcers of phthisical patients may be caused by swallowing tuberculous sputa, has been urged with some plausibility, especially in view of the fact that these ulcers have been produced by feeding animals with tuberculous substances. Tuberculous ulceration affects by preference the lower part of the small intestine. The solitary follicles and Peyer's patches are usually first involved, but tubercles may develop independently of these structures. The process often extends to the remainder of the small intestine and to the large intes-

tine. The solitary follicles, and the individual follicles of Peyer's patches become swollen, and undergo, first in their centre, cheesy degeneration. Whether the swollen follicle with cheesy centre can properly be called a tubercle, is a matter of dispute, the decision of which is not of great importance. The cheesy mass softens and a little ulcer is produced. This ulcer extends partly by an inflammatory process, but chiefly by the development of tubercles in its edges and base. These tubercles undergo cheesy metamorphosis and softening. The shape of the ulcer may correspond at first to that of a Peyer's patch, but its tendency is to extend transversely in the course of the lymphatics and bloodvessels. This direction is explained by the fact that the tubercles, to whose development the ulcer owes its progress, form chiefly in the walls of these vessels. The appearance of a fully formed tuberculous ulcer is characteristic. Its long axis is transverse to the axis of the intestine. (This rule is not without exceptions.) The ulcer may nearly encircle the lumen of the intestine. Tuberculous ulcers constitute the most frequent and important of the so-called annular or girdle ulcers. The edges of the ulcer are thickened, sinuous, and present an appearance often described as worm-eaten, from the presence of little excavations due to softened tubercles. Tuberculous granulations are usually recognized without difficulty, both in the edges and in the base of the ulcer. Tubercles are developed in the vicinity of the ulcers. Patches of little white tuberculous nodules, seated in the subserous tissue, can generally be seen on the peritoneal surface covering the site of the tubercle. These peritoneal tubercles are of great assistance in recognizing both the position and the nature of the ulcer. Upon microscopical examination, tubercles are found in the neighborhood of the ulcer in the muscular and other coats of the intestine. They are formed chiefly in the outer sheaths of the arteries and in the lymphatic vessels. As a rule, they present the typical giant-celled structure (p. 48). Woodward describes a transverse puckering of the mucous membrane in the neighborhood of tuberculous ulcers, from a tendency in the ulcer to longitudinal contraction. Partial cicatrization of tuberculous ulcers, resulting even in stenosis, has been observed in several instances. That the tuberculous ulcers ever completely cicatrize is improbable. These ulcers do not often lead to perforation of the intestine, and very rarely indeed to general peritonitis from perforation. Circumscribed peritonitis over the seat of the ulcer is common. Tuberculous ulcers are usually accompanied by more or less inflammation of the surrounding mucous membrane. The mesenteric glands are frequently swollen and tuberculous.

Syphilitic intestinal ulcers are infrequent. Only in a small number of cases has their origin from gummata been demonstrated. Syphilitic ulcers of the intestine are either round or transverse. They may form annular or girdle ulcers. Their edges are generally grayish-white, indurated, and fibrous; the base is also indurated and usually without much purulent secretion; the serous coat over the ulcer is often thickened, and may present cicatricial tissue containing little fibrous nodules. In the thickened walls and base cheesy nodules, which are doubtless gummata, are occasionally detected. The hard fibrous tissue forming the floor and edges of the ulcer is generally densely infiltrated with small round cells. These ulcers may be found in both large and small intestine. Their cicatrization leads to more or less contraction of the calibre of the intestine. Submucous gummata have been found with, and without, ulceration of the intestine, but they are extremely rare. They appear to be more frequent in congenital than in acquired syphilis. Syphilitic ulcers and strictures of the rectum are considered fully in works devoted to venereal diseases. According to Fournier,[1] syphilitic

[1] Fournier, Leçons rédigées par Ch. Porak, 1875, Paris.

stricture of the rectum may be due, not only to the cicatrization of ulcers, but also to a diffuse hyperplastic infiltration of the mucous and submucous coats. To this syphilitic infiltration he gives the name ano-rectal syphiloma. Birch-Hirschfeld[1] has described, as an occasional lesion of congenital syphilis, diffuse sclerosis of the intestinal mucous membrane which was found thickened by an infiltration of fusiform cells.

The symptoms of intestinal ulceration cannot well be considered apart from the morbid conditions on which the ulcers depend. In general the symptoms are not characteristic of ulceration. There may be tenderness on pressure if the ulceration be extensive, especially if it be seated in the large intestine. The nutrition of the patient is usually impaired. The character of the stools is often abnormal. There may be diarrhœa, with liquid and often bloody evacuations. On the other hand, constipation may be present, particularly if the ulcers be high up in the bowels. Symptoms are often referable to a coincident enteritis. The hemorrhage from intestinal ulcers may be so profuse or persistent as to prove the immediate cause of a fatal termination, but instances of this are rare. Ulcers may give rise to perforation and fatal peritonitis. They may cause fistulous communication. If cicatrization take place, constriction of the intestinal canal may be thereby produced, and this stenosis may be the cause of death. Syphilitic ulcers are particularly prone to cause stricture of the intestine, but the same result may follow dysenteric, simple inflammatory, and even in rare instances tuberculous ulcers. Typhoid ulcers do not lead to stenosis. Not very infrequently ulcers are found unexpectedly on post-mortem examinations, there having been no symptoms referable to them during life. The prognosis depends upon the primary morbid condition. The treatment also has reference to this state. In general the treatment indicated in chronic dysentery is applicable. Ulcers and strictures seated in the lower part of the rectum are open to inspection, and are treated by local applications and surgical procedures.

Duodenal Ulcer.

Chronic ulcer has the same anatomical characters in the duodenum as in the stomach, and is probably, like the latter, caused by the solvent action of the gastric juice. It is far less frequent than gastric ulcer, the proportion being as one to thirty of the latter. The situation is usually near the pyloric opening. In contrast with gastric ulcer, the ages of patients are generally between thirty and forty, and it occurs much oftener in men than in women. These are points to be taken into account in the diagnosis. The fact of its occurrence in some cases after severe burns of the skin is also to be borne in mind.

The local symptoms by which it is to be differentiated from gastric ulcer are as follows: Vomiting is oftener wanting, and, when it occurs, the intervals between its occurrence and the ingestion of food are longer. The ingestion of food does not occasion the same degree of gastric disturbance and consequent distress. Paroxysms of pain are apt to occur, having the severity and character of gastralgia. The pain, as in gastralgia, is sometimes relieved by taking food. The pain is referred to the right hypochondrium. Jaundice sometimes, but rarely, is associated with duodenal ulcer. From the occurrence of this symptom, either duodenitis or the situation of the ulcer near the opening of the *ductus communis* is to be inferred. Hemorrhage is as liable to occur as in cases of gastric ulcer. Blood may be vomited, but it is passed in larger quantity by the bowels. These points relating to hemorrhage are significant as respects the diagnosis. Cancer is excluded by the absence of tumor, of the gastric symptoms usually connected with that affec-

[1] Birch-Hirschfeld, Wiener med. Presse, No. 41, 1878.

tion, and of the appearance characteristic of the cancerous cachexia. Moreover, cancer usually occurs at a later period of life, namely, between 40 and 60 years of age.

Duodenal ulcers may cicatrize, giving rise to stenosis and consequent dilatation of the stomach. But cicatrization is rare. Perforation is apt to take place and give rise to fatal peritonitis. This result is sometimes prevented by adhesions of the duodenum over the site of the ulcer prior to the perforation. These adhesions may take place and rupture afterward occur, as in a case which was under my observation. Duodenal, like gastric, ulcer may remain latent until perforation occurs.

The treatment is essentially the same as in cases of gastric ulcer.

Embolism of the Superior Mesenteric Artery.

As stated in Part First, page 32, embolism of the superior mesenteric artery is followed by hemorrhagic infarction of the small intestines. Although this artery anastomoses freely with the pancreatico-duodenal and with the inferior mesenteric, it has been shown by the experiments of Litten[1] that its branches are so little tolerant of an insufficient supply of blood that their coats undergo a molecular alteration which suffices for the production of a hemorrhagic infarction before a complete collateral circulation can be established. The wide extent of territory over which this vessel is distributed, is an impediment to the rapid development of a sufficient collateral circulation which, even in arteries more favorably situated, often requires considerable time. About twenty cases of embolism of the main trunk or of the branches of the superior mesenteric artery have been recorded. The embolus itself can usually be detected, post mortem, without difficulty. The parts affected by embolism of the main trunk are the greater portion of the small intestine and the upper part of the large. The extent of intestine involved, of course, depends upon the size of the branch obstructed. The wall of the affected portion of intestine is swollen, œdematous, and more or less infiltrated with blood. There may be, in addition, large and small circumscribed hemorrhages in the intestinal coats. The mucous membrane especially is swollen, soft and infiltrated with blood; its surface is coated with a layer of blood or of blood-stained mucus. In certain places there may be loss of substance from necrosis of the mucosa. The solitary follicles, Peyer's patches and the mesenteric glands are frequently swollen. When the main trunk of the artery is occluded, there are hemorrhages also in the mesentery. At first circumscribed and subsequently general peritonitis result. If the artery become slowly obstructed, as by pressure, no effects follow.

The symptoms have been studied chiefly by Gerhardt and by Kussmaul.[2] Those to which they attribute diagnostic importance are the following: 1. A source for an embolus (organic disease of the heart was usually present). 2. Abundant intestinal hemorrhages, which cannot be explained by an independent disease of the intestine or by portal obstruction. 3. Rapid fall of temperature. 4. Pain in the abdomen, often resembling colic and often violent. 5. After a time development of tympanites, and perhaps of a recognizable exudation in the peritoneal cavity. 6. The evidence of embolism of other arteries of the body. 7. In rare instances the detection by palpation of sacs containing blood between the folds of the mesentery. Vomiting was present in many of the cases reported. The bloody stools often had a fetid odor. The blood was sometimes of a tarry consistence, at other times fluid or in clots. Occasionally no hemorrhage occurred. In that case the diag-

[1] Litten, Virchow's Archiv, Bd. 63, p. 289, 1875.
[2] Würzburger medic. Zeitschrift, Bd. iv. and v. 1864.

nosis is impossible. The symptoms develop suddenly and death usually soon follows, preceded by collapse. It does not seem to be absolutely fatal. In a case reported by Moos which recovered, the diagnosis of this affection was rendered very probable. The diagnosis in the favorable cases of Lereboullet was not so well established.

The objects of treatment, as stated by Gerhardt, are to check the hemorrhage, to prevent necrotic processes in the intestine, to repair the loss of blood and to favor the re-establishment of a collateral circulation. He says: "In what way these indications are to be best fulfilled future experience must decide." Moos treated his case which recovered, by rest, lukewarm nourishing broths, small doses of wine, and by the internal and external application of ice. A certain degree of doubt necessarily attaches to the diagnosis of this case.

Embolism of the inferior mesenteric artery is sometimes unattended by symptoms; at other times symptoms similar to those described were present. Only about six cases have been recorded.

Carcinoma of the Intestine.

Cancer of the intestine presents the same varieties as when seated in the stomach. The most frequent situation by far is the rectum. Here it is open to discovery and examination by the touch and vision. Next to the rectum, it is most frequently situated at the sigmoid flexure of the colon; next in the transverse colon. It is situated in the duodenum or jejunum, the lower portion of the ileum, the descending colon, the ascending colon, and the middle of the ileum, as regards relative frequency, in the order in which these parts are now enumerated. In these different situations it often produces obstruction by compression and stricture.

The cancerous growth, when it has reached a certain extent, if situated above the rectum, forms a tumor which may be felt through the abdominal walls. The problem is then whether or not the tumor be carcinoma. The diagnosis is to be based on the existence of radiating, lancinating pains, the age of the patient (over 40 years), the frequently nodulated character of the tumor, the occurrence of bloody stools, the evidence of hereditary predisposition, and the symptoms which denote the cancerous cachexia. Fecal tumors, enteroliths, and foreign bodies are to be excluded; also, sarcomas and the benign neoplastic growths, namely, fibromas, myomas, lipomas, cysts, and adenomas. These, as well as cancerous growths, may occasion obstruction at different situations in the intestinal canal. They cannot, in cases of obstruction, be excluded with certainty unless they are situated in the rectum. They cannot be differentiated from each other during life, and hence they are of pathological, rather than of clinical, interest. This brief reference to them, therefore, is all that is called for. Duodenal cancer is not easily differentiated from cancer of the stomach. The differentiation is not practically of importance. The association of jaundice points to the former.

Waxy Degeneration of the Intestine.

The character of the lesion known as waxy, lardaceous, and amyloid has been considered in the first part of this work (*vide* page 57). The intestine, as well as the stomach, is not infrequently the seat of this structural change. The alteration is generally present throughout both the large and small intestine, but is usually most intense in the lower part of the ileum. The mucous membrane may be the coat chiefly affected, or, in addition, the other coats may be involved. Usually the solitary follicles and Peyer's patches

escape, or are but slightly affected. In certain cases, however, the waxy change is most marked in these structures (Hayem). Neumann observed cases in which the muscularis mucosæ was predominantly affected. Waxy degeneration is not to be positively recognized without the application of iodine or other appropriate reagents. Simple inflammation of the mucosa is generally present in cases of waxy degeneration. Kyber denies that there is any tendency in this alteration to the production of ulcers. Tuberculous ulcerations are often present when the waxy metamorphosis is secondary to phthisis.

Waxy degeneration may be inferred when diarrhœa is a prominent and persistent symptom in connection with waxy degeneration of the liver, spleen, or kidneys, these organs being affected either singly or collectively, the latter being often the case. The lesion is rarely confined to the alimentary canal, and, if so confined, the diagnosis is impossible.

The lesion is a permanent one, and admits of only palliative treatment.

Certain structural affections of the intestine are important as causing mechanical obstruction to the passage of the intestinal contents. Hence, we may consider *obstruction of the bowels or obstipation* as caused, *first*, by structural affections, and, *second*, as dependent on causes other than lesions of structure, namely, on the impaction of feces, the formation of concretions called enterolithes, the introduction of foreign bodies, and on merely functional disorder. The term ileus or iliac passion, and other names, have been applied to cases of obstipation with the ejection from the mouth of the intestinal contents, or so-called stercoraceous vomiting. As the latter symptom occurs in connection with obstruction from various causes, the names based upon it have no special pathological significance and tend to produce confusion.

Obstruction from structural affections is not of very frequent occurrence. The statistical researches by Brinton, the whole number of promiscuous necropsies being 12,000, showed obstructions from various causes, exclusive of hernia, in the proportion of 1 in 280 deaths.[1] The lesions involving obstruction are the following: Intussusception, invagination or volvulus; strangulation from hernia within the abdomen; rotation of a portion of intestine upon its own axis, or upon the mesentery, and twisting of a portion of intestine around another coil of intestine; compression of one portion of intestine by another portion, or by a tumor situated exterior to the canal, and stricture produced by morbid growths within the canal or by the contraction following the cicatrization of ulcers. In these several affections obstipation is a common feature; but they differ in an important point, namely, certain of them causing only mechanical obstruction, and others involving, in addition, strangulation. This point of difference is to be taken into account with reference to diagnosis, prognosis, and treatment. The structural affections giving rise to both obstruction and strangulation will be first considered, and afterward obstruction by causes which do not occasion strangulation.

Intussusception.

Intussusception, or intestinal invagination, is the reception of one portion of the intestine into another portion. Generally the invagination is from above downwards, but in rare instances the lower portion is received into the upper. The latter, called retrograde invagination, according to Leichtenstern never becomes incarcerated and strangulated. It is certain that invagination may occur transiently, giving rise to no symptoms. In post-mortem examinations, especially in children, innocuous invaginations of the small intestine

[1] British and Foreign Medico-Chirurg. Review, October, 1867.

are not infrequently found; the invaginated portion is restored without difficulty, and, aside from the displacement, there are no morbid appearances. I counted as many as fifteen of such invaginations in the body of a child dead with typhoid fever. They have been observed especially after death from cerebral diseases, and they are supposed to occur during the last moments of life. It is only when the invaginated portion becomes incarcerated, giving rise to congestion, inflammation, etc., that obstruction and the symptoms of strangulation are produced. The lesion is then one of very great gravity, in the great majority of cases ending fatally. This is the most frequent of the lesions causing fatal obstruction. Of 169 cases of obstruction from various lesions collected by Phillips, 63 were of this class. An analysis of 600 cases by Brinton showed in 43 per cent. the obstruction to be from intussusception; and of 1541 cases of obstruction from all causes, analyzed by Leichtenstern, 442 were due to this cause.[1] The greater relative frequency of the affection, however, relates to childhood. In adults it is less frequent than other cause of obstruction.

Intussusception brings into apposition three layers of intestine, namely, an entering, a returning, and a receiving layer. The receiving layer is called the intussuscipiens, and the middle and inner layer the intussuseeptum. In the relation of the entering and receiving layers, mucous surfaces are in contact, and these do not become adherent. But serous surfaces are in contact in the relation of the entering and returning layers, and inflammation, excited at the point of entrance, leads to adhesion of these surfaces, extending more or less beyond this point. In this way the invagination becomes incarcerated. The vessels of the portion of the mesentery connected with the invaginated intestine are obstructed by tension. Congestion and swelling of the invaginated intestine ensue; it is dark colored and ecchymotic, and, at length, becomes gangrenous and sloughs away, if life be sufficiently prolonged. The obstruction is due to the swelling from congestion and the exudation of inflammatory products. Usually the obstruction is complete, but in rare cases the intestinal passage remains pervious although much contracted. In these cases the intussusception is usually in the large intestine. Peritonitis is apt to extend more or less around the seat of the invagination, leading to morbid attachment to the adjacent parts.

The invagination may occur at any point in the intestinal tract. Its most frequent seat is at the junction of the ileum and the cæcum. This is shown in cases of children, by the statistical researches of J. Lewis Smith.[2] Smith's account of the mode in which it generally occurs is as follows: "The intussusception not infrequently begins in the prolapse of the ileum through the ileo-cæcal valve, in the same way that prolapse of the rectum occurs through the sphincter ani. If death take place early, only a small portion of the ileum may have passed the valve. If the case be protracted, the tenesmus brings down more and more of the ileum with its accompanying mesentery. The constriction of the valve, which acts as a ligature, prevents the further descent of the ileum, and, the tenesmus continuing, the next step is the inversion of the caput coli, which is drawn into the colon by the descending mass; and unless the case terminate by sloughing or death, the ascending and transverse portions of the colon are successively invaginated. Not infrequently, the cæcum is the part primarily inverted and invaginated, and, descending along the colon, it draws after it the ileum which sustains its natural relation

[1] *Vide* Ziemssen's Cyclopædia, Am. ed., vol. vii.

[2] Statistical Researches relative to the Seat, Symptoms, Pathological Anatomy, etc., of Intussusception in Children. Am. Journ. of Med. Sciences, Jan. 1862. *Vide*, also, Smith on the Diseases of Children.

to the ileo-cæcal valve. These two forms of invagination—that in which the ileum, passing through the ileo-cæcal valve, successively inverts and draws after it the caput coli and the divisions of the colon, and that in which the caput coli is primarily invaginated, and, descending along the large intestine, inverts the latter, and draws after it the ileum—constitute the vast majority of cases of this disease in childhood." The invaginated portion may descend so low as to be felt and seen at the anus, and it may even protrude from the body. The invagination, however, may occur at any point in either the large or small intestine. In Haven's analysis of 59 cases it was seated in the small intestine in 23. Of the cases analyzed by Brinton, the intussusception was ileo-cæcal in 56 per cent.; iliac in 28 per cent.; jejunal in 4 per cent., and in the colon in 12 per cent. Leichtenstern's statistics of 479 cases gave 52 per cent. of ileo-cæcal and ileo-colic, 30 per cent. of ileac, and 18 per cent. of colic invaginations.

The causation in the majority of cases, probably, is formularized in the following quotation from Leichtenstern: "Paresis of a limited portion of the intestine, associated with vigorous peristaltic action, excited by any cause whatever, offers suitable conditions for invagination." In adults, the most frequent cause is a tumor of the intestine, particularly a polyp-shaped tumor, projecting within the intestinal canal. Such a tumor, by its weight drags down a portion of the intestine and thus mechanically causes intussusception. Furneaux has lately shown that fatty degeneration of the muscular tunic of the intestine, destroying its capability of contraction, is liable to occur in connection with obesity and with a similar degenerative change in other organs.[1]

Intussusception causing obstruction and strangulation, as already stated, proves fatal in the great majority of cases; yet the affection is by no means absolutely hopeless. The manner in which recovery usually takes place is of importance in its bearing on the treatment. The invaginated portion of intestine sloughs away and is evacuated, the entering and receiving portion at the point of entrance remaining adherent, and the perviousness of the canal being restored. Cases have been reported in which a large portion of invaginated intestine was thrown off, and recovery followed. Prof. Van Buren reported a case to the New York Pathological Society, in which five feet of intestine were passed *per anum*, the patient recovering. Prof. Peaslee exhibited at a meeting of the New York Academy of Medicine, 1865, five feet of intestine which had been passed *per anum* four months before the death of the patient. He also exhibited the intestines removed from the body of this patient after death. The small intestine was only 16 feet in length, the length of the large intestine being 5 feet and 10 inches. The invagination and sloughing had taken place in the small intestine at a distance of six feet from the duodenum. A stricture existed at this point; the intestine above was much dilated, and that below greatly reduced in size. The patient died from inanition dependent on the stricture of the intestine.[2] Dr. William Thompson, of Edinburgh, collected 43 cases ending in recovery.[3] Of Dr. Haven's 59 cases, in 12 the invaginated portion was passed per anum, and of these 12 cases 10 ended in recovery. This is the mode of recovery which is to be hoped for after incarceration and strangulation of the invaginated intestine have taken place.

The prominent local symptoms which enter into the clinical history of

intussusception are as follows: Pain is more or less prominent, at first paroxysmal as in colic, and after a time becoming constant, with frequent exacerbations. The pain, if the patient be old enough to describe it, appears to emanate from a certain fixed point. Tenderness at first may not be marked, but becomes developed, being either limited to, or greatest at, the point whence the pain emanates. The tenderness and constant pain denote the occurrence of peritonitis at the seat of the invagination. Vomiting soon becomes a prominent and persistent symptom, with very few exceptions. The vomited matter, after a time, may have the odor of feces, and is then said to be stercoraceous. The accumulation of ingesta and gas above the obstruction occasions more or less abdominal distension, provided the invagination be not situated in the upper portion of the small intestine. Frequently the accumulation of intestinal contents at the seat of the invagination gives rise to a tumor appreciable by the eye and touch, and to dulness on percussion. The tumor is elongated, "sausage-shaped," corresponding to the size and direction of the dilated intestine above the seat of the obstruction. After the contents of the intestinal canal below the seat of the obstruction have been evacuated, there is persisting obstipation, save in a few exceptional cases. Previously there is usually diarrhœa, followed by the discharge of bloody mucus, and, if the invaginated portion of intestine descend to the rectum, tenesmus is felt and the patient is led to make straining efforts. Under these circumstances the affection is liable to be mistaken for dysentery.

The general symptoms at first may not be marked, but soon they denote a grave affection. The pulse becomes accelerated, its frequency progressively increases and it is proportionally feeble or compressible. Progressive prostration, hiccough, coolness or coldness of the surface, an anxious or haggard expression, denote the progress toward a fatal termination. The mode of dying is by asthenia, the pain and tenderness frequently diminishing or ceasing for some time before death.

A favorable progress is denoted by the occurrence of free evacuations from the bowels, the discharge of the invaginated portion of intestine, together with improvement in all the local and in the general symptoms.

Invagination is to be distinguished from functional colic, acute peritonitis, and obstruction from other causes. The symptoms at first may denote nothing more than colic. The persistency of pain, the development of tenderness, the acceleration of the pulse, the vomiting, etc., however, soon point to an affection of greater gravity than colic. Acute peritonitis is to be excluded by the gradual development of the local and general symptoms; by the absence of diffused tenderness over the abdomen, and of rigidity of the abdominal muscles; by the localization of pain and tenderness within a circumscribed space, and by the presence of a characteristic tumor. Acute peritonitis sometimes supervenes, in cases of invagination, from rupture of the intestine above the obstruction. From obstruction caused by hernia within the abdomen, or by rotation and twisting of the intestine, the discrimination is more difficult, and, indeed, cannot always be made with positiveness. The age of the patient has a bearing on the diagnosis. Invagination occurs most frequently in infancy. According to Smith's statistics, it is most apt to occur between the second and third month of infantile life. Of 47 cases only 18 occurred between the ages of one year and twelve years. In Haven's cases the mean age was 18 years; the youngest age was 3 months, and the oldest 65 years. In Leichtenstern's statistics, half of the whole number of cases (473) occurred during the first ten years of life; one-fourth occurred after three months and within the first year of life. Male children are somewhat more liable to it than female, the relative proportion, in Smith's cases, being thirty-two to twenty-two, and in Haven's 59 cases 34

were males. On the other hand, hernial obstruction occurs oftener after infancy and childhood, and cases occur oftener in females than in males.

A point in diagnosis is to determine the probable seat of the invagination. The chances are that it is seated at the junction of the large and small intestine, especially in childhood. The probability of this being the seat is increased, if the pain, tenderness, and swelling are situated in the neighborhood of the right iliac fossa. Tenesmus, with the discharge of blood and mucus, shows that the large intestine is involved. The invaginated portion may sometimes be felt and seen within the rectum. If seated in the small intestine, the constitutional disturbance is greater, and, if the point of obstruction be toward the upper portion of the small intestine, there will be little or no abdominal distension. Indican is found in abnormal quantity in the urine in cases of intestinal obstruction from intussusception and other causes, but also in other affections of the alimentary canal.[1]

The prognosis is extremely unfavorable. The usual mode of recovery in the exceptional cases in which the affection does not end fatally, has been stated, namely, by sloughing away of the invaginated portion of intestine, the adhesions at the point of entrance being permanent. Possibly the invaginated portion is spontaneously restored, in some cases, after symptoms denoting the affection are developed, but such instances must be rare. And it is also rare for the invaginated portion of intestine to remain, the canal becoming or continuing pervious. Of the 50 cases analyzed by Dr. Smith, in 7 recovery took place, and in each case by sloughing. In all these 7 cases the ages were between 5 and 12 years, Dr. Smith's researches being limited to cases occurring in childhood. The constitutional powers in infancy do not seem to be adequate to support the affection for a sufficient period for the sloughing process to be completed. The separation of the invaginated portion of intestine takes place, according to Leichtenstern, in the majority of cases between the eleventh and the twenty-first day. In fatal cases, the duration rarely extends beyond eight days. Death may take place within twenty-four hours, the symptoms denoting "shock." In the majority of cases, life is not prolonged beyond the third day. In rare instances, the obstruction being incomplete, and the invaginated intestine not strangulated, the affection is tolerated for many weeks and months. There are cases, therefore, of chronic intussusception. Death sometimes is hastened by peritonitis caused by rupture of the intestine above the seat of the obstruction. In young children the duration is sometimes shortened by the occurrence of convulsions. Generally the mode of dying is by slow asthenia.

If the existence of invagination could be ascertained prior to the development of symptoms denoting incarceration, it is probable that measures for restoration might be successfully employed. But generally a day or two elapses before the character of the affection is even suspected. In the mean time, cathartics are likely to increase the invagination and diminish the practicability of restoration. The liability to the existence of this affection, especially in children, should be borne in mind in cases of apparent colic, and should dictate reserve in the employment of cathartics. As soon as the character of the affection is rendered probable by the symptoms, measures to effect restoration may be tried. These measures are the injection of water or of air in considerable quantity into the rectum. If practicable, the injection should be made through a long flexible tube carried into the intestine as far as it can be made to pass without undue force. The object is to effect the restoration by the upward pressure of the air or water. The injections are not to be pushed beyond the limit at which they are borne without much

[1] *Vide* article by Heineman, Archives of Medicine, New York, August, 1880.

suffering, and, if they do not succeed after a fair trial, they are not to be persisted in. They will very rarely succeed after the invaginated portion of intestine has become swollen by congestion and the peritoneal surfaces in contact have become adherent. If pushed too far, rupture of the intestine below the seat of the obstruction may be produced. I have known rupture to result from the injection successively of an acid and alkaline liquid, giving rise to the evolution of gas by combination within the intestine. This method of employing pressure is highly objectionable, because the amount of pressure cannot be regulated. Cases have been repeatedly reported in which the injection of air or water has apparently effected restoration in cases of supposed invagination, even after obstruction had existed for several days. But it is probable that in a certain proportion of these cases invagination did not really exist. These measures for reduction are, probably, of no avail if the seat of the invagination be above the ileo-cæcal valve.

Exclusive of measures for reduction, the objects of treatment are to secure as much quietude of the intestinal canal as possible, to palliate suffering, and support the powers of life, under the hope that sloughing and recovery may take place. The avoidance of cathartics is essential. The practitioner is not to be tempted to employ them with the hope of overcoming the obstruction. They interfere with the objects just named, and are destructive. Not only the active cathartics, but even mild purgatives and laxatives are contra-indicated. To quiet the peristaltic movements, opium is to be given in sufficient doses to secure relief of pain without inducing narcotism. Fomentations over the abdomen are useful. The strength of the patient is to be supported by concentrated and purely nutritious food given in small quantities at a time, together with alcohol. It is to be borne in mind that recovery will depend on life being sufficiently prolonged for the sloughing away of the invaginated portion of intestine. Bloodletting, counter-irritation, or any measures which tend to impair the vital forces, are never indicated, and cannot fail to do harm. After sloughing has taken place and the obstruction is removed, purgatives are not to be employed, lest, by exciting unduly peristaltic movements, the adhesions at the point of the invagination may be broken up and peritonitis ensue from the escape of the contents of the intestine into the peritoneal sac.

Important practical questions relate to the operation of abdominal section, or laparotomy, in cases of invagination. Heretofore this operation has been resorted to as a last resource, and, perhaps, for this reason, its merits were not fairly represented by its results. The first object of the operation is to restore the parts if practicable, and if this be not practicable, a second object is to perform enterotomy and establish an artificial anus. The chances for restoration are greater in proportion as the operation is resorted to early. After strangulation has existed for some time, it would not be advisable to restore the invaginated intestine were this practicable. After the time has elapsed for the practicability or safety of the restoration, the chances of recovery by sloughing away of the invaginated intestine are lessened by the operation, and it would have been better to have trusted to nature's method. Taking into view this consideration, together with more or less uncertainty as regards the diagnosis, surgeons have not been disposed to regard the operation with favor; and, in the previous editions of this work, doubts concerning its propriety were expressed. Within the past few years, however, experience has shown that laying open the peritoneal cavity is not attended with the danger formerly attributed thereto, and a number of cases have been reported in which the operation for invagination has been resorted to with success. Professor Sands, in 1877, operated successfully in the case of an infant, six months old, eighteen hours after the occurrence of symptoms

denoting invagination. In connection with his report of this case, he gives an analysis of twenty cases collected from different sources, in seven of which the operation was successful. The reader is referred to Prof. Sand's article for arguments in favor of the operation.[1] The important points in deciding respecting the operation in individual cases are, the correctness of the diagnosis, and the probability, or otherwise, that the invaginated intestine has not become gangrenous. The probable seat of the invagination is of importance with reference to enterotomy; but there is small hope of success from the latter operation if the restoration of the invaginated intestine be impracticable.

As a palliative measure, if the distension of the abdomen from tympanites becomes excessive, interfering with respiration, an aspirating needle may be passed into the intestine, and the gas in this way removed. Experience has shown that this procedure is devoid of danger, and it may be resorted to in cases of obstruction by other causes than invagination.

Reference has been already made to cases in which invagination may not involve complete obstruction, and is tolerated for several months. These are, of course, cases of invagination without strangulation. A remarkable instance has been reported by Dr. C. A. Leale. The patient was a woman 79 years of age. An attack of severe abdominal pain was followed by jaundice, bloody stools, tenesmus, complete fecal obstruction, and, from time to time, vomiting of intestinal contents. Five weeks afterward, on exploration of the rectum, an invaginated portion of intestine was felt. The finger, after considerable effort, was passed into the latter, and two quarts of pasty feces were subsequently voided. Eleven days afterward a solid body was felt at the opening of the invaginated bowel. This was broken into two pieces, and with considerable difficulty removed. It proved to be an enterolith, four and a quarter inches in circumference and two and a half inches in length, formed by concentric layers of stercoraceous matter around a biliary calculus three and a half inches in circumference. Restoration of the bowel was speedily effected by the injection of carbonic-acid water in large quantity. This patient was seen by me in consultation.[2] Jonathan Hutchinson relates the case of a child in whom the invaginated bowel extended several inches beyond the anus. The case had been treated as one of prolapsus ani. Abdominal section was made and the bowel restored with ease. Rapid recovery took place. The invagination in this case commenced at the cæcum.

Strangulated Hernia within the Abdomen. Rotation or Twisting of Intestine.

Several abnormal conditions lead to *hernia* within the abdomen. Fissures sometimes exist in the mesentery, meso-colon, omentum, and diaphragm, into which a portion of intestine passes and is liable to become incarcerated and strangulated. The vermiform appendix of the cæcum sometimes becomes adherent to an adjacent part, leaving a loop through which intestine may pass and become ligated. The same may happen in connection with diverticula of the intestinal tube, which are not very infrequent. The most frequent

[1] *Vide* New York Medical Journal, June, 1877; *vide*, also, article by Dr. John Ashhurst, Jr., in Amer. Journ. Med. Sciences, July, 1874; also article by Jonathan Hutchinson in the London Med. Times and Gazette, No. 29, 1873, and in New York Med. Record, January 15, 1874. Peyrot has collected 23 cases, of which 9 recovered. De l'Intervention Chirurgicale dans l'Obstruction Intestinale, Paris, 1880. This work contains an analysis of 125 laparotomies for intestinal obstruction.

[2] For report of Dr. Leale's case *vide* New York Med. Record, November 22, 1879.

and important of these is that known as Meckel's diverticulum. This represents a portion of the unobliterated omphalo-mesenteric canal, by which in the embryo the umbilical vesicle communicates with the intestine. It is connected with the ileum usually from a foot to three feet above the ileo-cæcal valve. From its extremity a solid cord containing the remnant of the omphalo-mesenteric vessels may pass to the umbilicus. Bands of adventitious membrane, resulting from peritonitis, may leave spaces for hernial protrusions. Various other forms of internal hernias have been described, some of which being very rare are rather curiosities than of practical importance. Much has been written concerning the so-called duodeno-jejunal hernia, of which between forty and fifty cases have been reported. In this form of hernia, first accurately described by Treitz, the small intestine makes its way into the duodeno-jejunal fossa, normally a small pouch situated in front of the vertebræ at the beginning of the mesentery. A crescent-shaped fold of peritoneum, passing over the duodeno-jejunal flexure, bounds the free opening of this fossa, which is directed upwards. All of the small intestine has been known to push its way into this fossa, which then becomes enormously distended. The intestines lie behind the peritoneum in this form of hernia. A very rare form of internal hernia is produced by the passage of portions of the small intestine through the foramen of Winslow into the cavity of the lesser omentum. Diaphragmatic hernia is more frequent on the left than on the right side. The intestines pass more frequently through the muscular than the tendinous part of the diaphragm, and oftener through the posterior than the anterior part. The organs usually involved in diaphragmatic hernia are, in the order of frequency, the stomach, the transverse colon, the omentum, and the small intestine. The hernia may be due to a congenital defect in the diaphragm. Acquired diaphragmatic hernia is most frequently referable to traumatism, as to a stab or gunshot wound. Rare forms of hernia which are not, strictly speaking, internal, but which are often difficult to detect by external examination, are the ischiatic, the obturator, the perineal, the lumbar. As regards the frequency of the different varieties of internal hernia, of Leichtenstern's 1541 cases, embracing obstruction from all causes, the strangulation was caused by false ligaments in 111, by the omentum in 58, by diverticulæ in 66, by the appendix vermiformis in 34, by the diaphragm in 215, and in other ways in 60. The cases collectively amount to 544.

Whatever be the mode in which the strangulation is produced, the symptoms are the same. They are, in fact, identical with the symptoms of ordinary strangulated hernia occurring at the femoral or the inguinal outlet, and they are, for the most part, the same as in cases of intussusception. The existence of tenesmus with bloody and mucous evacuations, in certain cases of the latter, constitute the chief point of distinction. Irrespective of the symptoms just named, the differential diagnosis can hardly be made with positiveness, but the chances are that in the young child invagination exists, whereas, in after life, obstruction from other causes is more liable to occur. The small intestine is far more likely to be the seat of hernia within the abdomen than the large intestine. Sloughing of the strangulated portion of the intestine is destructive, whereas, in cases of invagination, it is the mode of cure. The only hope of recovery is in the spontaneous reduction of the hernia before gangrene takes place. Distending the large intestine with air or water will, probably, be useless if the seat of the hernia be in the small intestine. Cathartics do harm. Opiates to palliate pain, fomentations to the abdomen, and supporting measure are indicated.

Rotation or twisting of a portion of intestine, so as to induce strangulation, is most apt to occur at the sigmoid flexure of the colon. An unusually small root of the sigmoid meso-colon favors torsion of this portion of the intestine.

The root of the meso-colon may be contracted by cicatricial tissue from an old peritonitis. Similar contractions may occur elsewhere. Torsion may occur at the cæcum, this portion of the large intestine being exceptionally mobile. Twisting of a portion of intestine around an axis formed of mesentery, or around another coil of intestine, occurs in the small intestine, or a coil of intestine may become looped around the sigmoid flexure, and *vice versâ*. These accidents are infrequent. Their symptoms are those of strangulation, and it is impossible to discriminate them from hernia within the abdomen. In the analysis of 600 fatal cases of obstruction from various causes, exclusive of hernia, rotation or twisting of intestine occurred in 8 per cent. In Leichtenstern's 1541 cases, 54 were in this category. In cases of obstruction and strangulation exclusive of invagination, the propriety of resorting to laparotomy is to be considered. Ashhurst (*op. cit.*) collected 57 cases in which this operation was performed. Of these cases, 18 terminated successfully, giving a mortality of a little over 68 per cent. There is this in favor of resorting to the operation in these cases, namely, the prospect of recovery without it is much less than in cases of intussusception. Ashhurst's conclusion embodies a proper rule of practice in these cases. It is as follows: "In cases of acute intestinal obstruction from other causes than intussusception, should milder measures fail to give relief in the course of three, or, at most, four days, laparotomy should be unhesitatingly recommended, and may, under such circumstances, be resorted to with a reasonable hope of success."

A highly important injunction is to be added to the consideration of obstruction dependent on the foregoing structural affections. It is, that the practitioner, in all cases which present the symptoms of these affections, examine carefully for inguinal or femoral hernia. The hernial tumor may be so small as not to excite the attention of the patient, and, in females, motives of delicacy may prevent the patient from suggesting an examination, even when the presence of a tumor is known to her. Instances have repeatedly occurred of patients dying with strangulated femoral or inguinal hernia which was overlooked, the symptoms being attributed to some inaccessible lesion, or even to functional disorder.

Compression and Stricture of Intestine.

Obstruction due to closure or diminished calibre of the intestinal tube by morbid growths within the tube, the pressure of tumors situated exterior to the tube, or constriction following the cicatrization of ulcers, differs from obstruction caused by the structural affections already considered, in not involving strangulation. The obstruction, under these circumstances, is developed gradually, having been preceded by progressively increasing constipation. Above the seat of the obstruction the intestine is dilated and filled with accumulated fecal matter. The muscular coat is hypertrophied. Below the obstruction the intestine is small, collapsed, and often atrophied. The obstruction is rarely complete. The local and constitutional symptoms incident to inflammation, sphacelation, and sloughing of the intestine are wanting. The symptoms are those arising from the gradual accumulation of the contents of the intestine above the point of obstruction. The affection progresses more slowly toward a fatal termination, after the obstruction becomes nearly or quite complete, than the affections which involve strangulation.

Cases of obstruction falling under this head form a considerable proportion of the cases of obstruction from all causes. Stricture of the intestine may be due to cicatrization of dysenteric, of syphilitic, of digestive, and of simple inflammatory ulcers, in rare instances to partial cicatrization of tuberculous

ulcers, to cicatrization of ulcers produced by irritant poisons, and of ulcers caused by sloughing of an invaginated portion of intestine. In exceptional cases, cicatrization of unusually extensive and deep-seated typhoid ulcers may be followed by stenosis. The contraction of newly-formed connective tissue, resulting from circumscribed or from general peritonitis, may cause constriction of the intestine. Both benign and malignant tumors may produce intestinal stenosis, either by pressure, or by invading in their growth the calibre of the intestine. The consideration of syphilitic and other strictures of the rectum belongs to surgery. In the majority of cases stricture is due to cancer of the intestines. According to the statistics of Coupland and Morris (1878), in three-fourths of the cases of stricture the seat is in either the rectum or the sigmoid flexure. The transverse and descending colon are more frequently affected than the ascending colon and the cæcum.

The discrimination of the cases of obstruction caused by compression or stricture from the cases involving strangulation, can generally be made, clinically, by means of the differential points which have just been stated.

The fact of the obstruction being seated in the lower part of the large intestine can generally be ascertained. If seated in the rectum, it is accessible to direct exploration. If seated at the sigmoid flexure, the fact is shown by the evidence, afforded by manual exploration, of distension of the transverse and ascending colon, and by the inability to inject liquid beyond the rectum. *Per contra*, the situation at the upper part of the large intestine or in the small intestine is shown by the absence of distension of the large intestine with intestinal contents, and by the ability to fill the colon with injected liquid. The obstruction may be complete, but, in general, a certain quantity of liquefied fecal matter passes the point of obstruction and is evacuated. The injection of liquids as a means of determining the seat of stricture is open to fallacies. Not only may the obstacle be due to other causes, such as a fecal collection, but liquids may pass beyond a stricture from below, although the occlusion be complete as regards the passage downward of intestinal contents. Simon's method of exploration by the passage of the hand into the bowel may be resorted to, giving due consideration to the care to be exercised in the operation and the possible danger of producing rupture of the intestine.

The distension from accumulation of the intestinal contents may lead to rupture of the intestine. The distension may gradually go on and lead to this accident without pain or other symptoms sufficient to direct attention to the existence of any serious obstruction. This fact was illustrated by a case under my observation at Bellevue Hospital, in which nothing more than ordinary constipation had been suspected, when peritonitis suddenly became developed, ending fatally in a short time. Obstruction was produced in this case by a cancerous tumor at the sigmoid flexure; the colon and cæcum were enormously distended with feces, and the peritonitis was due to rupture of the cæcum. This case illustrates the ability of the ileo-cæcal valve to resist an amount of pressure sufficient to lead to rupture of the cæcal walls.

In the treatment of obstruction from compression or stricture, active purgatives are to be avoided, but saline laxatives in small doses, in order to liquefy the intestinal contents, are indicated. Colic pains are to be relieved by opiates. The diet should be nutritious and concentrated, in order to leave as little fecal residue as possible. If the obstruction be situated at the lower part of the large intestine, careful efforts to pass a flexible tube beyond the constricted portion may be employed, and, if successful, liquid may be injected above the obstruction.

In cases of obstruction from compression or stricture at the lower part of the large intestine, colotomy with a view to the establishment of an artificial

anus is warrantable, provided other measures to free the intestine from an amount of accumulation likely to lead to rupture be not successful. Cases have been reported in which life has been prolonged and comfortable health obtained by means of surgical interference. Cæsar Hawkins reported the results of the operation for artificial anus in 44 cases. In 10 of these cases death took place within 48 hours, in 21 within five weeks, and in 13 the operation was successful. Of these 13 cases, 6 died in six months, and 7 survived more than a year. Professor Erskine Mason, in connection with 6 cases in which he had performed this operation, collected and tabulated 80 cases, exclusive of the 44 cases reported by Hawkins. The reader is referred to Mason's article for a full consideration of the claims of colotomy.[1]

Obstruction from Impaction of Feces, Gall-Stones, Enteroliths, and Foreign Bodies.

Obstipation may be produced by the causes named in the above heading, but in general they induce only more or less constipation, and, in treating of the latter affection, they will again be referred to. An accumulation of a mass or of masses of hardened feces sufficient to produce obstruction, may take place in different parts of the large intestine. The rectum in aged persons not infrequently is the seat of such an accumulation. It is to be suspected when enemas cannot be given, and perhaps the pipe of the syringe is found to penetrate a fecal mass. Examination shows the seat and the character of the obstruction. It may be necessary to break down and remove the accumulation by a scoop or the handle of a spoon. The accumulation may be at the sigmoid flexure, and then resistance to the passage of liquid injected and to the introduction of a flexible tube is found to be at that point. The accumulation may be at any point above the sigmoid flexure, but is oftenest in the cæcum or ascending colon.

Masses of feces above the sigmoid flexure may give rise to a tumor or to tumors appreciable by manual exploration through the abdominal walls. These fecal tumors are liable to be mistaken for others of a different character. A woman in the country presented an abdominal tumor of the character of which her attending physician was not satisfied, and an eminent professor of anatomy, now deceased, was requested to see the case. He was led to regard the tumor as malignant, and, of course, to form a very unfavorable prognosis. Shortly after the consultation a profuse diarrhœa set in, and, much to the astonishment of the patient and her physician, the tumor suddenly disappeared. It was a fecal tumor. I could cite other instances of a similar error. In view of the liability to error of diagnosis, and in order that appropriate measures of treatment may be pursued, the distinctive features of the tumors are to be borne in mind. One point in the diagnosis is their situation in the tract of the colon. Generally they are not tender on pressure, but may be handled freely without giving pain, but to this rule there are some exceptions. By firm and continued pressure they may sometimes be moved backward or forward in the direction of the colon. By firm and continued pressure, also, the form of the tumor may be altered.

The absence of pain, tenderness, vomiting, and of the constitutional symptoms accompanying invagination, internal hernia, and twisting of the intestine, suffices to exclude these affections; but it cannot be at once determined that the obstruction is not due to compression or stricture. The effect of measures

[1] *Vide* Am. Journ. of Med. Sciences, October, 1873. A considerable number of cases have been reported in different medical journals since the date of Professor Mason's article.

of treatment will be likely to settle the diagnosis. The measures to be employed are mild purgatives in small doses, repeated after short intervals, conjoined with large enemas given through a stomach tube carried upward to the sigmoid flexure. Active cathartics do not accomplish the object, and are liable to do harm. The object is to soften the harder collections, at the same time gently increasing the peristaltic movements. An emulsion of castor oil and a solution of the sulphate of magnesia or of soda are eligible purgative remedies. The bitter waters (Friedrichshall, Pulna, and Hunyadi Janos) may be found effective. The injections should consist of lukewarm water, to which syrup or mucilage should be added to obviate rapid absorption by the bowels. Some attach importance to the addition of ox-gall to the enemas. These measures, judiciously employed, will generally prove successful, without much delay, in relieving the obstipation and causing the fecal tumors to disappear. Mild purgatives may be required for some time after the obstruction is removed; the treatment, then, will resolve itself into that adapted to habitual constipation.

Obstruction may be due to the presence of large gall-stones, or of intestinal calculi or enteroliths. Gall-stones of sufficient size to produce obstruction usually escape into the intestine after fistulous communications have been formed between the gall-bladder and some part of the intestinal canal, as the duodenum. Large gall-stones may, however, pass through the greatly distended ducts into the duodenum. Obstruction produced by gall-stones is very rare, and is almost invariably situated in the small intestine. Intestinal concretions or enteroliths rarely exceed in man the size of a hazel-nut. In the horse and other herbaceous animals they are more common, and may attain an enormous size, weighing sometimes twenty pounds. These intestinal calculi in animals constitute a variety of the so-called bezoars, to which were formerly attributed remarkable medicinal virtues. The nucleus of these concretions in man is often formed by a gall-stone, by a hard mass of feces, or some foreign body as fruit-seeds, eggs of ascarides, indigestible aliment, etc. The concretions frequently present concentric layers. They are composed, for the most part, of phosphate of lime and of magnesia, mixed with carbonate of lime, biliary coloring matter and intestinal mucus. Concretions occasionally form in the intestine in consequence of the prolonged use of certain mineral drugs. In this way have been formed concretions composed of calcium carbonate, of magnesium carbonate, of magnesia and of iron. Indigestible constituents of the food, especially the fibres and husks of vegetables, may form a conglomerate mass of sufficient size to give rise to obstipation. All these varieties of concretions are most frequently formed in the cæcum and large intestine. They rarely attain sufficient size to produce any considerable obstruction. They may, however, prove serious obstacles in case a stricture of the intestine already exists. These obstructing bodies may be situated within the cæcum, at the sigmoid flexure, or in the rectum. They may sometimes be felt through the abdominal walls. They may lead to ulceration and perforation of the intestine, or, if not discharged and the obstruction be complete, vomiting of so-called stercoraceous matter ensues, and death may take place from exhaustion. An intestinal concretion, cuboid in form, the vertical and transverse diameter one and a half inches, its weight fifteen drachms, was sent to me by Dr. O. T. Jameson, which was found after death in the ileum just above the cæcum. It was distinctly felt through the abdominal walls during life, and had existed for over twenty years. The patient was a shoemaker, and experienced notable inconvenience from the concretion only at times after overwork, or after violent muscular exertion. He died of pneumonia, at the age of 47.

Finally, foreign bodies, that is, by way of distinction, bodies not contained in the aliment, nor derived from the body, may pass into the intestinal canal from the stomach, or be introduced into the rectum. In the latter case their presence is readily ascertained by exploration, and they are removed by appropriate surgical appliances. When introduced into the stomach, they have been swallowed either deliberately, as is done by jugglers, or inadvertently. Prof. Gross, in his comprehensive work on Surgery, cites the case of a man in Iowa, who swallowed a bar of lead weighing a pound, which was removed from the stomach by an opening made through the abdominal walls, and the patient recovered. The same author refers to another case in which a large teaspoon was swallowed in a fit of delirium, and this was extracted from the ileum by the operation of enterotomy.

Foreign bodies, not sufficient in number, or not large enough, to occasion obstruction, are often swallowed, especially by children. The practitioner is frequently summoned in haste, and great anxiety is felt when bodies such as pins, coins, portions of glass, etc., are known to have been swallowed. They may give rise to more or less irritation of the mucous membrane; they may even occasion ulceration and perforation of the stomach or intestines. In general, however, they pass through the alimentary canal without any appreciable inconvenience; and the physician is warranted in giving assurances of the absence of danger. It is not judicious, in such cases, to give cathartics or laxatives. The mucous membrane is best protected against injury, if a sharp-pointed or irritating body be contained in the solid contents of the bowels. Moreover, the increased peristaltic movements caused by a purgative increase the risk of injury. The desire to have anxiety relieved as quickly as possible, by ascertaining that the foreign body has passed, is an inducement to resort to purgation, which is to be resisted.

Functional Obstruction.

Persisting obstipation accompanied with vomiting of so-called stercoraceous matter, colic pains, etc., may occur as a purely functional disorder, constituting an affection which has been called *idiopathic ileus*. A person is seized with abdominal pain, increased paroxysmally; vomiting soon takes place, and, after a time, the matter vomited has the odor of feces; measures to procure evacuations from the bowels are ineffectual; the pulse becomes frequent, and there is more or less prostration. After the lapse of a week or more, these symptoms subside, free evacuations from the bowels ensue, and the patient recovers. These are the prominent features of a case which I reported many years ago.[1] The patient was a female, aged twenty-five; hysterical symptoms were associated; the treatment consisted of the free use of opiates, and enemas administered through the long flexible tube. In this case, the patient declared that she tasted castor-oil which was given exclusively per enema, and it was said that oil was observed to float on the matters vomited.[2]

Dr. S. B. Hunt subsequently reported a case in which obstipation existed for fifteen days, and during this period the patient vomited matter described as "horribly fetid and stercoraceous." This case was treated for the first five days by giving active cathartics. At the end of this time the condition

[1] Buffalo Med. Journal, vii. p. 530, 1851.

[2] That fluid injected into the rectum may pass the ileo-cæcal valve, and even ascend to the stomach, has been proven by two observations of Cantani. After injecting a quart and a half of oil into the rectum, a portion of the oil was vomited in about an hour. Virchow u. Hirsch's Jahresbericht, Bd. ii. p. 180, 1879.

was so unpromising that the cathartics were discontinued and a soothing treatment adopted with a view to euthanasia. Under the latter treatment the symptoms denoted gradual improvement, evacuations from the bowels occurred spontaneously, and recovery took place. This patient was a female, aged thirty-five, and a sufferer from symptoms connected with spinal irritation.[1]

Such cases simulate those of obstruction from the structural affections which have been considered, and there is ground for the belief that in a certain proportion of the reported cases of the successful treatment of invagination or strangulated hernia within the abdomen, the affection was purely functional. The regurgitation of the contents of the small intestine, which have a stercoraceous odor from the diffusion of the gases contained in the large intestine, in these as in other cases of obstruction, is generally attributed to an inversion of the peristaltic movement. Brinton explains it by supposing that in the centre of the intestinal tube a retrograde current is produced by the normal peristaltic movements, if there be an obstruction. The obstruction, when functional, may be caused by spasmodic contraction of the tube, or it may be due to paralysis of a portion of the tube and consequent failure of this portion to propel its contents.

The clinical discrimination of functional obstipation from obstruction caused by structural affections, cannot always be made at once with confidence. The absence of tumor and of pain and tenderness localized at a particular point, tends to the exclusion of the latter. The functional character of the affection may be surmised if the patient be a female subject to hysteria, and suffering from the nervous symptoms associated with so-called spinal irritation. The probability of the affection being functional is increased in proportion as the obstipation, with vomiting, etc., continues, without the supervention of the symptoms which occur after sphacelation of intestine has taken place, namely, frequency and feebleness of the pulse, coldness of the surface, extreme prostration, great tympanites—in short, the symptoms denoting impending death by asthenia.

In the treatment of functional obstipation, opium and other measures to relieve pain and allay spasmodic action are indicated. Cathartics may be cautiously tried, but, if ineffectual, they should not be persisted in. Enemas administered by means of a long flexible tube are to be employed.

The importance of examining for the evidence of femoral and inguinal hernia is to be enjoined in connection with the subject of functional obstipation.

CHAPTER V.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE.

Acute Dyspepsia. Chronic Dyspepsia. Polyphagia, Malacia or Pica. Polydipsia, Dipsomania. Gastrorrhagia.

OF the functional disorders of the stomach and intestine, a large proportion relate to digestion, that is, to the processes involved in the changes which the ingesta undergo in the alimentary canal. The processes of digestion take place chiefly within the stomach and small intestine. The greater part of the functional disorders of digestion are commonly embraced under the name *dyspepsia*. This name signifies simply difficulty of digestion, but, conventionally, it is applied to cases in which the digestive processes are disturbed in various ways, as well as to the cases in which their performance appears only to be difficult. It is, however, convenient to make a distinction between simply difficult digestion, that is, dyspepsia in the literal sense of the term, and disordered digestion; the latter may be distinguished as indigestion. Generally, dyspepsia denotes ailments which are sufficiently persisting to be considered as chronic. The term *acute dyspepsia*, however, is applied to a disorder of the digestive organs, attended with comparatively violent symptoms, and having a short duration. The disorder so called claims a brief notice.

The term *acute dyspepsia* denotes an affection called by French writers *embarras gastrique*, and popularly known with us as a *bilious attack*. When accompanied with more or less febrile movement, it is sometimes called *gastric fever*. The latter term is objectionable, because it implies that the affection is essentially a fever, whereas the febrile movement is symptomatic. The term bilious attack is also objectionable, because it is by no means clear that the pathology of the affection involves special disturbance of the liver. In the absence of precise knowledge of the pathological character of the affection, the term acute dyspepsia is to be preferred, inasmuch as, pathologically, it expresses no more than a functional disorder pertaining to digestion. The term, in fact, is applied to cases embracing, probably, different morbid conditions.

In certain cases of acute dyspepsia, the difficulty is expressed by calling it a fit of indigestion. Gastric disorder is occasioned by over-repletion of the stomach, the ingestion of indigestible articles of food, or an arrest of digestion by strong emotions, fatigue, or other causes. The disorder is manifested by a sense of weight, fulness, or pain in the epigastrium; nausea and perhaps vomiting may occur, or, after a time, looseness of the bowels ensues; some febrile movement may be induced, with pain in the head and general malaise. Succeeding these symptoms are loss of appetite, coating of the tongue, an unpleasant taste, with more or less uneasiness referable to the digestive organs for several days. Such cases are sufficiently common. In the way of treatment, they claim only a mild evacuant remedy, and regulated diet for a few days, with, perhaps, some tonic remedy.

The practitioner meets often with cases which differ from the preceding in the disorder not being distinctly referable to a fit of indigestion. There is

impairment or total loss of appetite; nausea and slight vomiting may occur, but oftener a liquid containing bile is regurgitated; uneasiness or undefined distress is felt in the neighborhood of the stomach; the bowels are sometimes constipated and sometimes loose; the patient complains of a bitter taste, and the breath is frequently offensive; the tongue becomes furred or coated; pain in the frontal region of the head is a frequent symptom which, if accompanied by nausea, goes by the name *sick headache;* the urine deposits in abundance the lithates; in some cases there is moderate febrile movement; the countenance frequently presents a sallow appearance. Patients imagine that their malady is very clearly defined when they declare that they are bilious. It is frequently, if not generally, difficult to trace the affection to any cause. It occurs undoubtedly oftener in the spring than in other seasons of the year. It continues a few days, and gradually the normal condition of the stomach and system is regained. It is probable that in many, if not most, cases of acute dyspepsia, there is subacute gastritis. In certain cases the affection is that called by some authors catarrh of the stomach, to which reference has been already made.

Patients with acute dyspepsia are apt to desire active treatment. They fancy they need cleansing remedies, and in this light they regard emetics and cathartics; or they solicit medicines to act upon the liver. Readjustment of digestion, etc., takes place without medication, but a mercurial cathartic often appears to afford prompt relief. A few grains of calomel or blue mass, followed by a saline purgative, and, afterward, a mild tonic such as a grain or two of quinia two or three times daily, with regulated diet, are appropriate measures of treatment.

The term *dyspepsia*, without the prefix *acute*, is applied to a more persistent affection than that just considered. As the name of a functional affection, it is not correctly used when applied to disorders of digestion connected with inflammation or structural lesions of the digestive organs, or to disorders incident to fever and other general diseases. The term is much less frequently used now than formerly. One reason for this is, formerly the term had a wider latitude than now, embracing affections which progress in pathological knowledge has placed nosologically elsewhere. But the affection is undoubtedly less prevalent than it was half a century ago in this country.

The symptoms of dyspepsia are, in the first place, local, that is, referable directly to the stomach or small intestine, and, in the second place, manifested elsewhere, in other words, sympathetic or consecutive. The local symptoms, which will be first noticed, are varied in character, and might serve as a basis for the subdivision of dyspepsia into several varieties.

These symptoms are conveniently classed as follows: *First*, symptoms denoting labored or difficult digestion, that is, dyspepsia in the literal sense of the term; and, *second*, symptoms proceeding from imperfect or disturbed digestion, that is, indigestion.

In certain cases, the processes of digestion appear to be fully accomplished, but they are accompanied with uncomfortable sensations. In healthy persons, as is well known, a good digestion is productive of a sense of comfort. It is quite the reverse in some dyspeptics. They are often uneasy or miserable while the digestive processes are going on; they complain of uneasiness in the stomach or intestine, of a sense of distension, and of a general sense of discomfort. And these symptoms may afford the only evidence of disorder. The food appears to be digested, and the body may be well nourished, whereas, in other cases, these symptoms are associated with those denoting imperfection or disturbance of the digestive processes. On the other hand, when

digestion is incomplete or disturbed, various symptoms arise in different cases, and with these there is sometimes comparatively little suffering. It is a curious apparent inconsistency that some persons manifest habitually more or less derangement of digestion without much annoyance, while other persons habitually digest perfectly but pass a wretched existence. The more prominent of the local symptoms in cases characterized by indigestion, may be arranged under the following heads: Regurgitations, including pyrosis, cardialgia, tympanites and vomiting.

Certain cases are characterized by regurgitations from the stomach. The liquid regurgitated is sometimes intensely sour from the presence of lactic, butyric, acetic or other organic acids. If the regurgitations occur, as is usual, during the progress of stomach-digestion, the acidity is due to chemical changes in the ingesta, but occurring, as is sometimes the case, after long fasting, when the stomach contains no food, it may come from the gastric glands. The presence of the hydrochloric acid in the stomach may prevent the chemical changes in the ingesta, and hence, this acid is sometimes a remedy in cases characterized by acidity of eructations. The regurgitated liquid is sometimes acrid, appearing to scald the throat; it may be greasy, or nauseous, having the odor and taste of rotten eggs, the latter denoting putrefactive changes. Some persons possess or acquire the faculty of voluntary regurgitation, and are able to expel, at will, the contents of the stomach—a faculty analogous to that of rumination in herbivorous animals.

The regurgitation of a considerable quantity of a liquid which is either insipid, or saltish or brackish, and sometimes acid, when the stomach is empty of food, and usually in the morning, is called pyrosis or water-brash.

Cardialgia signifies pain at the cardiac orifice of the stomach, of a burning character, shooting into the chest, and up the œsophagus into the throat. It is vulgarly called heart-burn. Every one has occasionally experienced this symptom. It characterizes certain cases of indigestion, and is evidently dependent on the presence of an acid in the stomach, as it is quickly and completely relieved, for a time, by an alkaline remedy.

A painful sense of fulness after eating is common without any abdominal distension; but more or less distension from air or gas is a prominent symptom in certain cases, constituting tympanites. The tympanites may be situated in the stomach or small intestine. In most cases the gas is derived from putrefactive or fermentative changes in the ingesta. The nature of the gas will depend on the kind of food ingested. In the decomposition of albuminoid substances sulphuretted hydrogen is produced, and the gas expelled from the stomach has a characteristic fetor; the butyric fermentation furnishes hydrogen and carbonic acid gas, and the latter is also furnished by the acetic fermentation. The formation of lactic acid is unattended by the production of gas. The accumulation of gas within the stomach, if considerable, occasions painful distension, embarrasses respiration by interference with the descent of the diaphragm, disturbs the action of the heart, and interferes with the gastric peristaltic movements. The formation of gas resulting from over-repletion of the stomach, may distend the stomach to such an extent as to cause sudden death. Two instances of this kind have fallen under my observation.[1]

Another source of flatulent distension is from gas secreted or evolved in some way independently of chemical changes in the ingesta. The accumulation is especially in the small intestines. Some persons suffer from an habitual tympanites. Females are more liable to it than males. Cases are occasionally met with in which the rapid development of tympanites occasions great

[1] Reported in Boston Med. and Surg. Journal, March 10, 1841.

suffering, the abdomen becoming enormously distended, the respiration embarrassed by interference with the descent of the diaphragm, and, in females, the suffering being increased by pressure upon the uterus and bladder. In a case under my observation paroxysms of intestinal tympanites, occasioning intense distress, had occurred daily for several successive months, an inodorous gas sometimes passing off by the rectum, and sometimes the tympanites disappearing without any escape of gas. A host of remedies had been employed in this case unsuccessfully, and at length improvement took place under simple palliative treatment. In a case of this description, the appearance of the abdomen during an attack of tympanites was extraordinary. The convolutions of the small intestine and their peristaltic movements were distinctly visible through the distended abdominal walls. So far as my observation goes, such cases occur only among females, and the tympanites is associated with more or less neuropathic disorder. Hysterical phenomena are sometimes associated with it.

There is another source of flatulent distension, the seat of the tympanites being the stomach, namely, the ingestion of air. More or less air is habitually commingled with food and drink, but the quantity received in this way is never sufficient to distend the stomach. A habit of swallowing air is sometimes acquired, resembling crib-biting or wind-sucking in horses. Some writers refer to this habit as not uncommon, but the effort required in the deglutition of air is such that the act could not escape detection; and, judging from my own experience, cases are by no means frequent in this country. In a case which came under my observation, the patient was about fifty years of age, and had suffered from a disorder of the digestive organs for twenty-five years. In order to show how he performed the act of swallowing air, he drank a quantity of water precipitately, and appeared to make violent efforts to force it downward. During these efforts the face became flushed and the eyes watery. Shortly the efforts were discontinued, and at the same moment a loud gurgling sound was heard in the region of the stomach. It appeared as if there were some obstruction in the œsophagus, but a probang was readily passed into the stomach. The patient stated that the habit had existed for twenty-five years. He was led to it gradually in order to prevent regurgitation which he stated always occurred if he failed to ingest air in conjunction with his food and drink. He was accustomed to belch air frequently. Percussion over the stomach showed considerable gastric tympanites. He declared that he could not overcome the habit, but promised to make the attempt. Nothing was heard of the case afterward.

An habitual tympanites of the stomach occasions, in some persons, after the ingestion of liquid, a succussion sound in walking, resembling the sound frequently heard in horses. This is a source of much annoyance and mortification, especially to women. It may be avoided by taking into the stomach only very small quantities of liquid at a time. This symptom alone is not proof of dilatation of the stomach.

Vomiting is not common in cases of chronic dyspepsia. It is more frequent in occasional fits of indigestion. It is, however, characteristic of a form of chronic dyspepsia occasionally met with, occurring generally in young girls. In this variety of disorder, vomiting almost constantly follows the ingestion of food or drink; the stomach seems to be intolerant of all forms of nourishment, although taken in small quantities. The vomiting occurs directly or soon after food is taken, and, in some cases, it is surprising that there is not more evidence of inanition, since everything taken into the stomach appears to be ejected; yet, although the disorder may continue for a long time, the patient does not become greatly emaciated nor notably enfeebled. The disorder is apt to resist all the usual remedies to relieve irritability of the

stomach, such as bismuth, creasote, opiates, hydrocyanic acid, oxalate of cerium, etc. It is usually accompanied with mental depression, hyperæsthesia of the surface, and marked tenderness over the spinal column. In determining that the affection is purely functional, gastritis, gastric ulcer, subacute meningitis (especially in children), pregnancy and disease of the kidneys are to be excluded. Restricting the patient to milk or some other article of diet in very small quantities, repeated at very short intervals, will sometimes succeed. But the plan of treatment which, in my experience, has proved most successful, consists in change of scene, and living as much as possible out of doors. I have known a sea-voyage to prove efficacious.

The local symptoms just noticed are not peculiar to dyspepsia or indigestion as a functional affection. They may occur in connection with subacute gastritis and structural lesions of the stomach. In arriving at the diagnosis—that is, determining that a functional affection only exists—inflammation and the lesions which have been considered are to be excluded. They are to be excluded by the absence of their diagnostic symptoms, and for these the reader is referred to the preceding chapters.

Of symptoms other than those referable directly to the digestive organs, mental disorder is one of the most noticeable. During the processes of digestion, dyspeptics are apt to experience an uncomfortable heaviness or dulness, rendering it difficult to concentrate the attention upon any subject. The following extract from Chambers's work gives a graphic representation of the condition in many cases: "There is great languor and incapacity for exertion, coming on generally about an hour after food, and accompanied in some cases by an almost irresistible drowsiness, which lasts for several hours. This symptom is particularly marked in the afternoon, if the patients dine in the middle of the day and endeavor to continue their employment afterward. Yielding to the drowsiness and taking a siesta seem to make matters worse, for there is usually felt after such an indulgence an intense headache or giddiness, which continues longer than the symptoms would have done had the inclination to sleep been resisted. The depression of spirits is not so remarkable as the feeling of utter helplessness, both of mind and body, accompanied in persons naturally active with a sense of shame at their unwonted apathy."[1] This condition may be connected with the process of digestion in the small intestine, and may be unaccompanied by symptoms denoting disorder of stomach-digestion.

In most cases of dyspepsia, patients suffer more or less from mental depression. They are devoid of buoyancy, gloomy, and disposed to look always on the dark side. Frequently this depression is increased by anxiety respecting health. They are apprehensive of the existence of some grave disease, such as consumption or an affection of the heart. Their attention becomes concentrated upon themselves. They are constantly watching the sensations connected with digestion, and fall into the habit of counting the pulse, feeling the heart's beat, examining the abdomen, urine, etc. This mental disorder, carried beyond a certain point, eventuates in melancholia and hypochondriasis.

In addition to these symptoms of mental disorder, various symptomatic phenomena belong to the clinical history of dyspepsia. Irregular action of the heart, or palpitation, is not uncommon. Constipation generally exists, sometimes alternating with diarrhœa. The skin is apt to be dry and rough; the extremities are often cold, showing deficient activity of the circulation; the tongue is usually furred or more or less coated. The urine deposits the lateritious sediment, and, on microscopic examination, crystals of oxalate of lime

[1] Digestion and its Derangements. American edition, page 367.

may be found in abundance—the latter, being incidental to various morbid conditions and not uncommon in connection with trivial disorders, are incorrectly considered as denoting a special affection called *oxaluria*. Vigilance is a frequent source of complaint, and the sleep obtained is often incomplete and disturbed by dreams, the patient arising in the morning unrefreshed and miserable.[1] The appetite in the morning is often poor, becoming, perhaps, during the day, morbidly craving. A dry hacking cough is reckoned among the sympathetic phenomena, but this is rare. The existence of cough should always excite suspicion of pulmonary disease or of chronic pharyngitis.

With reference to the pathology of dyspepsia and indigestion, it is to be considered that digestion is not a simple process. Including under this term all the changes which take place in the ingesta within the alimentary canal, there are certain changes in the stomach from admixture with the salivary fluids and the gastric juice, others in the duodenum from the addition of the bile and pancreatic secretion, and others in the small intestine, below the duodenum, from the action of the intestinal juice. For the proper activity of the organs, and for the secreted liquids, the latter being vastly more abundant than was formerly supposed, a large supply of blood is required. The movements due to the muscular coat of the stomach and intestine are important. A certain influence derived from the nervous system is requisite for the secretion of the liquids and the peristaltic movements. An analysis of the symptomatic phenomena in different cases of dyspepsia shows that the different elements which enter into the function of digestion may be affected either separately or with different degrees of predominance. Thus vomiting and regurgitation show irritation and spasmodic action; pain or distress, morbid sensibility; prolonged digestion with chemical changes, deficiency in the digestive liquids, etc. It is of importance to take cognizance of these several elements in the management. The period which elapses after eating before the inconvenience is felt, and the absence of symptoms of disorder referable to the stomach, go to show that the affection is intestinal rather than gastric.

The causation involves agencies affecting the digestive processes either directly or indirectly. Excesses in eating and drinking act as direct causes. The digestive powers may be overtasked by the quantity, or over-excited by the quality, of food. Under these circumstances, dyspepsia has been called "the remorse of a guilty stomach." The habit of spirit-drinking engenders dyspepsia; drunkards after a time become dyspeptics. Dyspepsia may follow subacute gastritis or enteritis produced by dietetic error or other causes; inflammation leaves the organs in a weakened state. These direct causes, however, are not so largely operative as is generally supposed.

The indirect, more than the direct, agencies are involved in the causation. These are various. Anæmia is one of the indirect causes. It gives rise to dyspepsia by diminishing the functional activity of the gastric and intestinal glands, the digestive liquids being lessened, or affected in regard of their quality. Clinical observation shows that, in cases of anæmia, the digestive power is generally more or less weakened. On the other hand, impaired digestion may stand in a causative relation to anæmia. A notable change in habits as regards physical exercise is not infrequently causative. The vigor of the digestive organs is in a measure commensurate with the demand for nutritive material, and the latter is dependent on the waste of the tissues. Now, certain dietetic habits are formed in accordance with occupations in-

[1] The poet Cowper, who appears to have suffered from intense mental depression in connection with dyspepsia, describes his feeling in the morning in the following forcible language: "I awake like a toad out of Acheron, covered with the ooze and slime of melancholy."

volving physical activity and a proportionate amount of disassimilation. Persistence in these dietetic habits after a change from an active to a sedentary life is apt to induce disorder. This is, in part at least, an explanation of its occurrence among those who exchange the farm or workshop for the desk or study, and among those who retire from business to enjoy leisure.

In a large proportion of cases, dyspepsia originates and is perpetuated by mental causes. It is induced and kept up by anxiety and depression. Disorder is often, in the first place, produced by mental causes, and then reacts upon the mind, increasing its morbid condition. An examination into the previous history of cases will frequently show the affection to have been preceded by mental inquietude of some sort. Persons of a certain mental constitution are especially prone to dyspepsia, namely, those so constituted as to be constantly anxious about something, such as acquiring success in life, getting out of debt, securing an independent position, or about imaginary troubles. The period of life when persons are most prone to dyspepsia is that in which anxieties are apt to be greatest, namely, between adult age and middle life. After the latter period, the events of life are taken more calmly, and there are fewer sources of intense anxiety. Persons who have been dyspeptics for many years are often free from this affection after having entered upon middle life. It may be doubted if the affection be often produced by overtasking of the intellect. When it occurs in those who are devoted to intellectual pursuits, it arises generally from the sedentary habits connected with these pursuits or from mental anxiety; on the other hand, deficient exercise of the intellectual and moral faculties is apt to lead to it. Conditions in life involving ennui and dissatisfaction predispose to it. Under these circumstances the attention is apt to become concentrated on the functions of the body, which go on best without close surveillance. These views are sustained by observing the classes of persons who suffer from dyspepsia. Epicures and gormandizers by no means of necessity become dyspeptics; they often escape this affection when their indulgences lead to other consequences, such as gout, etc. The laboring classes are not prone to dyspepsia, notwithstanding the use, frequently, of the coarsest and most indigestible kinds of food, prepared without any regard to the art of cookery. But cases are met with especially among retired rich persons without occupation or mental resources, among those who have no useful or proper aims in life, and among those who are debarred from the interests of domestic life; in these several classes it may be developed irrespective of any dietetic errors.[1]

Treatment.—In the management of dyspepsia, as of other affections, the first point is to remove or obviate causes as far as this is practicable. The practitioner may be able to control causes relating to dietetic errors, but he may not be able to reach those connected with the mind, and hence a difficulty in effecting a cure. Measures of treatment may be arranged in three divisions, namely, 1st, those relating to diet and regimen; 2d, measures addressed to the mind; and, 3d, medicinal remedies.

1. If the affection have been induced by dietetic excesses, it is sometimes useful to give the digestive organs a short period of rest, and, with this view, to reduce the diet, for a time, below the wants of the system. This, however, should be but temporary. A cure is not to be effected by persisting in this course. Not only the system is reduced, but the digestive functions are impaired by too great or too protracted abstemiousness. Dyspepsia is, in fact, perpetuated, and may be produced, by attempts to live on as little and

[1] For a fuller exposition of these views of the causation of dyspepsia, *vide* article by the author in the American Journal of Med. Sciences, January, 1841.

as coarse food as possible. Persons who think it vulgar, unrefined, or worldly minded to eat well, are apt to be subjects of dyspepsia, as well as of other affections. This is true also of those who fancy that most maladies arise from over-eating, and that the great problem of health-preservation is to learn to eat prudently. The object of treatment is to bring the digestive powers up to such a point of improvement that particular care in diet is not requisite.

As regards the diet for dyspeptics, there are no rules suited to all cases. Individual experience, in each case, is not to be altogether ignored, but there is a liability to error in regard to this experience. Unusual difficulty of digestion, or indigestion, after a meal is often imputed to certain articles of food, when it was due to some other incidental circumstance. Idiosyncrasies in relation to particular articles of food are far less common than the statements of patients would lead one to suppose. In general, articles which are wholesome to most persons are not unwholesome to any. It is rarely true that "what is one man's meat is another's poison." As a rule, when a patient says that he cannot take such and such articles which general experience shows to be digestible and nutritious, it is fair to presume self-deception, and of this the patient may generally be convinced if persuaded to persist in their use. At first, the expectation that an article will prove hurtful contributes to render it so; but, after a time, the idea is overcome. It is often an object in the treatment of dyspepsia to do away with these fallacious ideas respecting various kinds of food. Some persons are fond of encouraging the notion that their digestive organs are endowed with peculiar susceptibilities which prevent them from conforming to general rules of diet. Their egotism is gratified by the thought that they differ in this regard from the common herd. In most cases animal food is best digested, especially old and tender meats plainly but well cooked; but, in some cases, a milk and farinaceous diet is found to agree best. An obvious reason why so many persons imagine they do not digest milk well is, it is apt to be taken as a beverage after or with solids, the fact that it is, in effect, a solid article of food not being appreciated. Bread, to be readily digestible, should not be new, nor is it desirable that it should be stale. Well-boiled rice, corn-meal mush, and other analogous farinaceous preparations, are easy of digestion. Crude vegetables are digested with more difficulty, but they are not, as a matter of course, to be interdicted. Some dyspeptics find even the much-abused cucumber grateful to the stomach as well as to the palate. Pastries, rich puddings, and sweetmeats are generally to be eaten sparingly or discarded. Ripe fruits in proper moderation are useful. It is never advisable for the patient to adopt a restricted range, or any particular system of diet. On the contrary, it is important to persevere in attempting to digest all the varied forms of wholesome food, not being restricted to meat or a vegetable diet, but aiming to eat like persons in health, without the need of particular care in the selection.

Different kinds of food are suited to different cases according as the functional disorder is chiefly gastric or intestinal. If gastric, farinaceous articles will be likely to be best suited, as these are digested mainly in the small intestine. Fatty articles may be well digested in these cases. On the other hand, if the disorder be intestinal, farinaceous and fatty articles of food will be likely to be difficult of digestion, and albuminoid substances or an animal diet will be found to occasion less inconvenience.

Restriction to a few meals a day is not an uncommon error. If a patient have no appetite for breakfast, an early lunch should be taken. If the dinner be near the middle of the day, and an early tea be taken, some light food in the evening is advisable. Long intervals between the periods of taking food tend to weaken the powers of digestion. Food should be eaten slowly. Deliberate mastication prepares the food for the action of the gastric juice.

Moreover, slowness in eating gives the stomach a chance to express satiety, and is, therefore, a protection against over-eating. Errors, however, in this respect are apt to be overestimated.

With regard to the use of wine or spirits, the danger of intemperance is always to be considered, especially as dyspepsia not infrequently leads to a morbid desire for stimulants, and in view of the fact that the mental state is favorable for the formation of intemperate habits. Yet an alcoholic stimulant taken with meals is often useful until the normal powers of the digestive organs are restored. Stimulants should never be taken when the stomach is empty.

It may be well to remind the practitioner that it is unphilosophical to judge concerning his patients from the conclusions derived from his own personal experience. The physician who has his notions of what kinds of food agree with himself best, is apt to apply these notions indiscriminately to his patients.

To consider fully the subject of dietetics would be incompatible with the scope of this work; but, practically, this is less desirable than many might suppose. My experience has led me to adopt a plan of dietetic treatment which has the merit of great simplicity, and which I have found to be very successful. I am accustomed to say to patients that if they expect to acquire a good digestion, they must not pay particular attention to diet; that they must follow the dictates of instinct rather than any precise rules, as respects the articles of food, the quantity to be taken, and the time of taking it. I have never known a dyspeptic to recover vigorous health who undertook to live after a strictly regulated diet, and I have never known of an instance of a healthy person living according to a strict dietetic system who did not become a dyspeptic. On the other hand, in a great number of cases, in which persons had been sufferers for years on a regulated diet, health has been speedily regained by simply eating in accordance with appetite.

As regards regimen, the clothing of dyspeptics should be such as will secure uniformity of temperature and maintain the functions of the skin, without over-accumulation of heat or exciting perspiration. A sense of comfort is the criterion in this regard. Exercise is of importance; but to be useful, it must be taken with a motive and end, aside from the sanitary object. Exercise, taken simply as exercise, tends to keep the mind of the patient on the disorder, and will not be likely to be persisted in. There is a risk of resorting at once to over-exercise, a too violent change of habits in this regard proving hurtful and discouraging the patient. The exercise should be in the open air. A change of business from one requiring sedentary habits to one involving out-of-door occupation is often advisable. Travelling, especially in foreign countries, where the attention is diverted with a succession of novel scenes, is highly useful. Sir James Johnston said that no case of purely functional dyspepsia could resist a pedestrian tour over the Alps.

2. The moral treatment consists first in establishing confidence by attention and sympathy. Inattention to the details into which dyspeptic patients are fond of entering, and ridicule of hypochondriacal fears prevent the physician from being of service to this unhappy class of patients, and lead them to seek for aid from secret remedies and quacks. If the confidence of the patient be secured, the assurances of the physician will often remove needless apprehensions, and afford an encouragement which, in itself, will contribute not a little toward improvement. If the patient be convinced that his mental state is in a measure due to a disordered condition of the body, he derives consolation and encouragement from this belief. The treatment relating to the mind will embrace, as far as possible, measures having reference to the removal of mental causes which may have produced or which perpetuate the affection. It is important to incite to occupations which divert

the attention from the bodily functions, especially during the process of digestion. It is desirable that the mind should be pleasantly occupied. It is often observed by dyspeptics that if they dine alone, and are left by themselves to watch the sensations connected with digestion, they are sure to suffer, whereas they experience no inconvenience from a greater amount of indulgence in eating if they be in agreeable company during and after dinner. Popular works on indigestion do harm by directing to the subject the attention of those prone to dyspepsia. The benefit of travel is, in a great measure, moral, involving recreation as well as exercise, and keeping the mind occupied with extrinsic subjects.

3. The division of the treatment which relates to medicinal remedies, relatively, is least important, but by no means unimportant. If the symptoms denote morbid sensibility of the stomach, counter-irritation on the epigastrium is often useful. Small blisters, the strong aqua ammoniæ, or the croton oil, may be used for this purpose. The benefit is, probably, in part, due to a moral effect. The nitrate of silver may be given in these cases, care being taken not to continue it too long. If anæmia be associated, the chalybeate tonics are indicated, of which, in cases of dyspepsia, the tincture of the chloride of iron is one of the best. The addition of an equal part of dilute phosphoric acid, and of the syrup of ginger or orange, makes this an agreeable remedy. The citrate of iron and quinia is an excellent form of tonic in dyspepsia associated with anæmia. The powder of iron reduced by hydrogen is another eligible form. If there be constipation, the bowels are to be regulated by appropriate measures, but purgation is to be avoided. Constipation will be considered as a distinct functional affection. There are no special indications for mercurial remedies except as an occasional cathartic or laxative. In general, the various vegetable tonics are useful, the form of tonic being varied from time to time. A grain or two of quinia twice or thrice daily, continued steadily for several weeks, appears to be often useful. A few drops of hydrochloric acid after eating, may frequently be prescribed with advantage. The benefit of the tincture of the chloride of iron is, probably, in part, due to the hydrochloric acid. Pepsin, in doses of five or ten grains, after each meal, appears often to be of service. The principle on which it is employed, namely, to supply a deficient element in the gastric juice, entitles it to be considered only a palliative, not a curative, remedy. A convenient and eligible form in which pepsin may be given is the preparation commonly known as rennet-wine. This is prepared by putting a fresh rennet, cut up into small pieces, into a pint of sherry wine, which, after maceration for two weeks, is to be strained, and it is then ready for use. Of this preparation, from half a teaspoonful to a teaspoonful is to be given shortly after taking food. I have used, for several years past, with great satisfaction, as a stomach tonic, salicin, in ten grain doses, dissolved in a wine-glass of water and taken just before each meal. The benefit derived from this remedy is often remarkable.

Symptoms characterizing certain cases of dyspepsia claim particular remedies. Pyrosis is generally relieved by bismuth in doses of a scruple or half a drachm combined with a carminative, such as powdered cinnamon, in conjunction with measures relating to diet, regimen, etc., and followed by tonic remedies. Cardialgia calls for alkaline remedies, namely, lime-water, liquor potassæ, bicarb. of soda, magnesia, the two latter especially if there be constipation. Flatulency and tympanites are to be relieved by carminative stimulants, the tincture of the essential oils, the aromatic powder, and charcoal powder, the latter being useful on account of its faculty of absorbing gases. All these remedies however, are merely palliatives. The conditions on which depend the several symptoms just named, are, if possible, to be removed by

tonic remedies, such as salicin, quinia, and the mineral acids. Tympanites occurring in paroxysms, from the secretion of gas, is an extremely obstinate form of disorder. Purgatives are not useful. Opiates to relieve present suffering are required. Carminatives and alcoholic stimulants will sometimes afford relief. Assafœtida given by the mouth or rectum is highly useful, especially when hysterical symptoms are associated. In the intervals between the paroxysms, measures, medicinal and hygienic, to invigorate the system are indicated, together with the use of antispasmodic remedies, such as belladonna, valerianate of zinc, etc. Small doses of strychnia, or of nux vomica in the form of tincture or extract, are useful in these cases.

The management in certain cases of dyspepsia characterized by persisting vomiting after taking food, has been already alluded to. Change of scene and out-of-door life are the most efficient measures. A sea-voyage will be likely to prove effectual. But various remedies may be employed in succession, each of which will sometimes be found useful, if not successful. The salts of morphia or codeia may succeed if the patient be not unpleasantly affected by opiates of any kind. The hydrocyanic acid, in some cases, is an efficient remedy. Creasote sometimes acts efficiently, given in doses of one or two minims, repeated after each act of vomiting. In young children this remedy, given in doses of one-eighth or one-sixth of a drop, frequently acts like a charm in arresting vomiting. Bismuth in large doses is a valuable remedy in some cases. Strychnia or the nux vomica has been found useful. The oxalate of cerium, from two to five grains at a dose, is another useful remedy. Counter-irritation on the epigastrium, by means of blisters or dry cupping, is frequently followed by relief. Milk, with lime-water added, is sometimes retained when other articles of food are rejected. Vomiting is symptomatic of a great variety of affections, exclusive of inflammation or structural lesions of the stomach. Occurring as a form of functional disorder of the stomach, it is sometimes considered as an individual affection; but it may with propriety be included under the head of dyspepsia.

There is a variety of vomiting which claims a brief separate notice. Reference is had to cases in which a liquid is thrown from the stomach in greater or less abundance, emitting an odor of fermenting wort, and, after standing a few hours, becoming covered with a mass of brownish froth resembling yeast. Goodsir, in 1842, on subjecting this liquid to microscopical examination, discovered in great abundance a vegetable fungus, which is now commonly known as the *sarcina ventriculi*, called by Robin *merismopœdia ventriculi*. The sarcinæ are distinguished by their oblong or square form, and by their being divided by lines into four equal squares, so that they resemble a package tied with a cord, as the name sarcina denotes. The vomited liquid containing sarcinæ may also contain the yeast-fungus in abundance. The liquid is sour, according to Budd, from the presence of acetic acid, and the vegetable productions are incidental to a process of fermentation attended with the formation of this acid together with the evolution of carbonic acid. There does not appear to be ground for the belief that the presence of the vegetable productions is the source of disorder. Their production within the stomach appears to be owing to an undue retention of its contents, from pyloric obstruction or other causes. The treatment, therefore, relates, not alone to the circumstances immediately involved in their production, but to the morbid conditions giving rise to these circumstances. Remedies, however, designed to arrest the fermentative process are indicated. And, of these, the most efficient is the bisulphite of soda. From fifteen grains to a drachm may be given, dissolved in water, two or three times a day. The sulphite of soda, and the other sulphites, are valuable as palliatives whenever, from defective power of digestion, fermentative processes in the ingesta take place. The

value of these remedies, in cases of dyspepsia, depends on their power in arresting fermentation.

Dyspeptics frequently derive advantage from the use of mineral spring waters, especially if connected with a sojourn, under agreeable circumstances, at a pleasant watering-place. Much of the advantage, doubtless, is due to the change of habits, relief from care, together with the moral influence of the expectation of improvement. Of the various mineral waters, those from the gaseous and chalybeate springs are best suited to cases of dyspepsia. Cold sea-bathing and the invigorating influence of a bracing sea-air are frequently useful. The hygienic discipline of the hydropathic system is undoubtedly useful in some cases, the benefit being due, probably, in part, to a physical, but more to a moral effect. There is, perhaps, no affection in which the anticipation of improvement from the employment of certain measures contributes to their efficacy more than in dyspepsia.

Polyphagia, Malacia or Pica, Polydipsia, and Dipsomania.

These names express morbid conditions which relate to the ingestion of solids or liquids; conditions which, severally, do not constitute individual affections, but which may be the most prominent, or perhaps the chief, ailments, and, therefore, they claim a passing notice.

Polyphagia, or, as it is more commonly called, *bulimia*, denotes a craving for food beyond the wants of the system. As thus defined, these terms are not correctly applied to the greatly augmented appetite felt frequently during convalescence from fevers and other acute diseases, or when, from any cause, the system for a time has been deprived of alimentary supplies adequate to its needs. The inordinate desire for food, under these circumstances, is an expression of the requirements of the system, and the ability to digest food may be proportionately augmented—a fact which illustrates, in a striking manner, the connection existing between nutrition and the function of digestion. True bulimia does not exemplify this physiological connection; the amount of food craved far exceeds the requirements for nutrition. Bulimia may be another name for gluttony. The love of eating may be cultivated to such an extent that little else is thought of, and persons who fall into this habit may be said to live to eat, rather than eat to live. The observation of every one will furnish examples of this kind. Habits of gluttony may lead to dyspepsia which, by interrupting further indulgence, proves conservative, or, if the digestive function continue active, they may lead to obesity, fatty degeneration of the heart or other organs, and to various affections. Voracious eating characterizes certain cases of mental derangement. It may be a symptom of disease attended with progressive waste, for example, diabetes. In a more marked and rare form, the craving for food greatly exceeds that under the circumstances just named. Curious instances have been reported, in which the morbid appetite appeared to be insatiable, all kinds of food, raw meat, candles, etc., being eaten, in some cases, with avidity, and in enormous quantity. It is difficult to explain the morbid appetite in these instances. Recovery from this condition may be expected. The indications are to regulate the diet as far as possible, to establish the general health by hygienic measures, to correct any disorder of digestion which may exist, and to palliate the excessive craving for food by opium or, sometimes, by nauseant remedies. Swallowing pieces of ice has been found effective as a palliative measure.

Malacia and *pica* are terms applied to perversions of appetite, that is, to a morbid craving for particular substances. The terms are commonly used

as synonyms, but, strictly, they denote different kinds of perversion. Malacia denotes a morbid craving for certain articles of food or articles which are not devoid of nutrition, whereas pica denotes a desire for innutritious substances. The craving for strange kinds of food, sometimes attending pregnancy, and commonly known as "longings," is sufficiently familiar. Similar eccentricities of the appetite are sometimes observed in connection with hysteria, and they may be due, in some cases, to that desire to become objects of wonder or interest which weak-minded hysterical women sometimes evince. Unnatural and disgusting perversions of the appetite are among the symptoms occasionally met with in cases of insanity. Perversions falling under the head of pica are sufficiently common. Innutritious substances frequently craved are charcoal, chalk, slate, and certain kinds of earth. The habit of eating these substances is sometimes carried to a great extent. In the case of a young woman seized, shortly after marriage, with epidemic dysentery which proved fatal, the dejections contained an enormous amount of a black substance which, on investigation, was found to be from a species of slate-stone which she was accustomed to eat daily in excessive quantity. In some cases of pica, the articles are at first taken with the idea of improving the complexion, and in this way the habit is formed. But, in other cases, a morbid uneasiness in the stomach leads to their use. The appetite is mostly confined to females, especially young girls, and is generally associated with anæmia or chlorosis. The measures of treatment are to be addressed to the associated disorders, the continued indulgence of the perverted appetite being interdicted.

Dirt-eating, as it is vulgarly called, (*chthonophagia*) is a morbid habit which heretofore prevailed, to a considerable extent, among the plantation negroes of the Southern States. It was described by John Hunter as prevailing among the negroes of the West Indies. The kind of earth selected is a loam or clay. Duncan gives the following account of this form of pica: "A very common disease among negroes on plantations in this part of the country (Louisiana), is a *state of anæmia* very often attributed, and perhaps justly, to the pernicious habit of *dirt-eating*. On examining negroes on a plantation, a medical man is surprised to meet with so many of these cases. Almost every large plantation has three or four, and sometimes more of them. . . . . With many, no doubt, dirt-eating is a symptom only of a diseased condition of the digestive organs, and of the system generally. With them dirt-eating proceeds from the same propensity which leads white females to resort to chalk, magnesia, etc., in order to relieve a disordered acid condition of the stomach. This condition of system is often, in my opinion, produced by a deficiency of suitable nutriment."[1]

Polydipsia is a term applied to denote a condition characterized by an excessive craving for liquids. Water is drunk in a very large or enormous quantity, amounting sometimes to several gallons in the twenty-four hours. In some cases the patient experiences constant or frequently recurring thirst, associated with dryness of the tongue and fauces. There is inability to sleep except for short periods, in consequence of the urgency of the desire for drink. The quantity of urine is proportionately great, so that this condition is also denoted by a term expressing the latter fact, namely, *diabetes insipidus*. The urine voided is of low specific gravity, presenting a clear limpid appearance like pure water, and containing neither sugar nor any abnormal constituent. In other respects, the health may not be notably disordered. The appetite and digestion may be unimpaired, the functions generally are well performed, and the body does not waste. This condition at first sug-

[1] Fenner's Southern Reports, vol. i.

gests to the physician the probable existence of diabetes mellitus, but an examination of the urine leads to the exclusion of the latter disease. The condition may occur in early life or become developed at any age. It has been observed to occur as an intermittent malady, but, in general, it continues for an indefinite period or during life. It does not appear to lead to any disease, and is serious, in itself, only on account of the annoyance and debility which it occasions. Its pathological character, with our present knowledge, cannot be satisfactorily explained. Existing to the extent just described, it is so rare as to belong among the curiosities of clinical experience. In our ignorance of the pathology, there are no rational indications for treatment, and experience has not furnished any reliable means of cure. Opium, valerian, camphor, and other antispasmodics have been found to diminish the thirst temporarily, and some benefit has been derived from the use of various tonic remedies.

Dipsomania is a term sometimes used to denote the peculiar delirium arising from the abuse of alcohol, but it is commonly applied to an uncontrollable desire for alcoholic drinks. A craving for this class of stimulants is sometimes developed in cases of dyspepsia, and may prove a source of intemperate habits. This fact has been already referred to. It is not to be lost sight of in judging of the propriety of prescribing or sanctioning the use of alcoholic stimulants in dyspeptic cases. A morbid craving for alcohol in some form is an element of intemperate habits whatever may have been their source. The habitual drunkard feels a desire for continued indulgence, which, with an impaired power of self-control and lessened self-respect resulting from intemperance, he is, after a time, wholly unable to resist. It is useless, under these circumstances, to attempt to reason him into temperance; he may appreciate the force of all the arguments which are presented, but he lacks moral strength enough to govern an acquired appetite which represents a morbid condition as much as the delusions of insanity. Reason and persuasion, however, may be effective before this condition of dipsomania is reached; that is, they may prevent this condition by leading to abstinence from alcoholic stimulants. Dipsomania is to be treated as a disease of body and mind. The cure is to be effected by withdrawing the patient from the use of alcohol in any form, and the employment of medicinal and hygienic measures to invigorate the physical and mental faculties. The treatment must be continued long enough for the cessation of the morbid craving for stimulants, and for the development of moral strength sufficient to enable the patient to adhere to a course of total abstinence in which alone consists safety. It is evident that successful management is rarely practicable, except by means of institutions in which the patient is under the same restrictions as in insane asylums. In fact, dipsomania is to be treated as a form of mental derangement.

There is a species of dipsomania which is constitutional and congenital. The desire for stimulants is paroxysmal, and an irresistible craving is developed by any indulgence, however small. Persons with this idiosyncrasy lose their power of self-control as soon as they feel the influence of alcohol. The only protection in such cases is in rigid abstinence.

Connected with the subject of dipsomania are questions pertaining to the causes of intemperance, and the means of its prevention, which are of the utmost importance to the welfare of mankind, but which do not properly fall within the scope of this work. The morbid effects of alcohol upon the system, aside from the development of dipsomania, will be referred to in connection with different individual diseases, and especially those affecting the nervous system.

Gastrorrhagia.

Hemorrhage into the stomach, and vomiting of blood, are denoted by the term *Hæmatemesis*. The term *Gastrorrhagia* is in uniformity with the rule of nomenclature by which a hemorrhage and its situation are expressed, and is, therefore, to be preferred. Moreover, the term gastrorrhagia applies to all cases of gastric hemorrhage, whether vomiting take place or not, the blood sometimes not being expelled by the mouth, but passing into the intestinal canal and being evacuated from the bowels. In the great majority of the cases in which hemorrhage takes place into the stomach, blood is vomited; and, more or less blood also passing into the intestinal canal, the stools present appearances to be described under the head of enterorrhagia.

When blood is expelled from the mouth, the first point is to ascertain the source of the hemorrhage. It may be from the mouth or posterior nares. Coming directly from either of these sources, it is traced without difficulty; but if blood be swallowed and vomiting occur, it may sometimes be a question whether gastric hemorrhage exists or not. In cases of bronchorrhagia, blood may be swallowed and vomited. In a child too young to expectorate, bronchial hemorrhage might thus be supposed to be gastric. Examples have occurred, but both bronchorrhagia and gastrorrhagia in young children are rare. The rupture of an aneurism into the pharynx or œsophagus is another source of hemorrhage which may appear to be gastric. But, in general, the question is, whether the blood come directly from the stomach or the air-passages. The points involved in this differential diagnosis have been already presented in treating of bronchorrhagia.[1] Blood which has been vomited, in most cases presents a dark grumous appearance. Exceptionally, it is florid, like arterial blood. It then comes from an artery, and has been vomited directly it accumulates within the stomach.

Gastric hemorrhage in the vast majority of cases has no claim to be regarded as an individual affection. It may be a symptom of carcinoma of the stomach, or of gastric ulcer, and, as such, has been already considered. It is an effect of portal congestion in cases of cirrhosis of the liver, and of obstruction of the vena portæ from a thrombus or the pressure of a tumor. It co-exists with hemorrhage in other situations in cases of purpura hæmorrhagica and scorbutus. It occurs in cases of acute gastritis, in acute yellow atrophy of the liver and in relapsing fever. It is a prominent event in the natural history of yellow fever; the so-called black vomit, in this disease, denoting neither more nor less than gastrorrhagia. Exclusive of these pathological associations, it may occur in place of the menses in cases of amenorrhœa. Instances in which gastrorrhagia is vicarious are by no means common. In the majority of the cases in which it follows suppression of the menses, it proceeds from disease of the stomach. Yet, that it may take the place of the menses, must be admitted. The cessation of habitual hemorrhage in some other situation, the arrest of purulent discharges of long standing, and the healing of old ulcers, have been supposed to stand, occasionally, in a causative relation to gastrorrhagia, but this supposition does not rest on adequate clinical proof. Hemorrhage sometimes occurs from the stomach, as from the bronchial tubes, the Schneiderian membrane, and in other situations, without any apparent pathological connections, neither following nor preceding any appreciable morbid conditions. It is then to be considered as idiopathic or as constituting an individual affection. Several cases have come under my observation, one of which, the hemorrhage extremely profuse, I have reported in another work.[2] Examinations after death have shown the absence of ulceration, erosions, or any appreciable solution

[1] *Vide* p. 269.

[2] *Vide* Clinical Medicine, p. 253.

of continuity, and the hemorrhage is then to be attributed to diapedesis. Hemorrhage from the stomach is an occasional event in pregnancy. It may be caused by a contusion received on the epigastrium. Irrespective of its occurrence as a symptom of gastritis, yellow fever, acute yellow atrophy of the liver, purpura hæmorrhagica and scorbutus, gastrorrhagia occurs oftener in women than in men. It is a rare event in new-born children, occurring a few hours after birth, the blood being vomited and also passed from the bowels. It proves fatal in some of these cases.

The prognosis, in cases of gastrorrhagia, will depend upon its pathological import. The prognosis is, of course, unfavorable if it be associated with gastric carcinoma or yellow atrophy and cirrhosis of the liver, although, under these circumstances, death is rarely an immediate effect of the loss of blood. If, however, the hemorrhage be vicarious, or not connected with any appreciable morbid conditions, the prognosis, as a rule, is favorable. The loss of blood, in proportion as it is considerable or large, induces debility, anæmia, and may prove the direct cause of death. The amount and rapidity of the hemorrhage may be such as to induce sudden death from syncope. On the other hand, a vicarious hemorrhage, if moderate, is not only without danger, but may conduce to the welfare of the system, so long as the menstrual discharge remains suppressed. In determining the amount of hemorrhage, it is to be borne in mind that the quantity of blood vomited is not always a criterion. The blood may accumulate and coagulate within the stomach without being vomited. The hemorrhage may be sufficient to destroy life, although the quantity vomited be not large. Death may take place in such cases as in cases of concealed uterine hemorrhage after labor. Evidence of hemorrhage being out of proportion to the amount of blood vomited, is afforded by dulness of percussion over the distended stomach, and symptoms denoting loss of blood, namely, feebleness of the pulse, coldness of the surface, pallor, faintness, etc. The blood thus accumulating within the stomach, if not vomited, passes into the intestines and is discharged by stool (melæna). Hemorrhage into the stomach has been known to occur and death take place from the loss of blood without any vomiting.

The treatment of gastrorrhagia has been already referred to in connection with gastric ulcer. The general principles of treatment having reference to the arrest of hemorrhage, and the prevention of its recurrence, are the same under whatever circumstances it occurs. With reference to these objects, perfect rest of body and mind is important. If the hemorrhage be profuse, or if it recur, rest of the stomach should be secured by withholding from this organ all nutriment, and nourishing the patient exclusively by rectal alimentation. Alcoholics, if indicated, are to be given *per enema*. Opium is useful by quieting the peristaltic movements of the stomach. It should be given hypodermically. The direct refrigerant effect of iced water taken in small quantities at a time, or of swallowing small pieces of ice, is useful. In urgent cases, as a means of arresting the hemorrhage, ice may be applied to the epigastrium. In less urgent cases, revulsive measures may be relied upon, namely, sinapisms and dry cups, applied in different situations over the abdomen. Hot, stimulating footbaths are useful by way of revulsion. Hæmostatic remedies, such as ergot, the acetate of lead, tannic acid, etc., if introduced into the stomach, are liable to excite vomiting, and thereby do harm. Ergotin may be given by hypodermic injection. Purgatives are contra-indicated.

These measures are to be employed, in individual cases, according to the urgency with which the arrest or the prevention of hemorrhage is indicated. If there be ground for regarding the hemorrhage as vicarious, interference will be required only to keep it within proper limits. This statement will also apply to hemorrhage occurring in pregnancy.

The treatment in most cases of gastrorrhagia, of course, embraces other measures than those having reference to the arrest and the prevention of the hemorrhage, namely, measures addressed to the morbid conditions with which the hemorrhage is associated. The latter are considered under other heads. So, also, measures called for after the occurrence of gastric hemorrhage, having reference to debility and anæmia dependent on the loss of blood, need not be here considered. After a considerable hemorrhage, the stomach, assuming the non-existence of cancer or ulcer, is enfeebled, and the liability to a recurrence of the hemorrhage is to be kept in view. Careful regulation of the diet, quietude of the body, and the avoidance of all disturbing agencies, are important during convalescence. Although profuse or repeated hemorrhages involve more or less immediate danger, patients may recover even when the loss of blood occasions prolonged syncope and extreme anæmia. Striking illustrations of this fact have come under my observation.

Gastric hemorrhage is sometimes simulated by hysterical females, and by malingerers among soldiers and prisoners. Blood obtained from animals, and even human blood, may be taken into the stomach, and vomiting excited by various means. This deception may be suspected in the case of a young woman who manifests a morbid disposition to impose on the credulity of those around her, as regards her ailments, when the symptoms do not denote loss of blood, when there are no grounds, aside from hemorrhage, to suspect gastric ulcer, and when the menses are not suppressed. Among soldiers and prisoners, it is to be suspected when the usual effects of hemorrhage are not apparent, and when the morbid conditions with which gastric hemorrhage is usually associated are wanting. The microscope may be of use in the detection of this kind of deception. Bennett cites a case in which a specimen of blood, which it was pretended had been vomited, was found to present the characteristic red corpuscles of the blood of a bird.

Leube mentions as an occasional sequel of gastrorrhagia, double and permanent amaurosis, pallor of the papillæ and attenuation of the retinal arteries being the only appearances revealed by the ophthalmoscope. That the amaurosis is simply an effect of anæmia, is disproved by the fact that it persists after the anæmic condition disappears. He therefore infers the existence of some connection between the nerves and vessels of the stomach and certain parts of the brain, an inference sustained by the occurrence of gastric hemorrhage after injuries to certain parts of the brain.

CHAPTER VI.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE—(CONTINUED.)

Inanition. Gastralgia. Passage of Gall-stones. Diarrhœa. Enterorrhagia.

IN addition to the ailments embraced under the head of dyspepsia, are various functional affections of the stomach and intestines. These will be considered in the following order: Gastralgia, including gastric spasm, and, in this connection, the passage of gall-stones or hepatic colic may be most

conveniently considered; diarrhœa and hemorrhage from the bowels or enterorrhagia; enteralgia and the affections known as saturnine or lead colic; sporadic and epidemic cholera.

Before entering upon the consideration of the affections just enumerated, I will offer a few remarks on a pathological condition which is not, perhaps, entitled to rank in the nosological catalogue as an individual disease, but which is an element of all diseases compromising alimentation and digestion. The pathological condition referred to is *inanition*. The importance of a due appreciation of this condition in medical practice renders it desirable to devote to it some attention, and it may with propriety be noticed in connection with the functional affections of the alimentary canal.

Inanition.

Health requires the assimilation of nutriment adequate, in quantity and kind, to the wants of nutrition. Every one is familiar with the mental and physical exhaustion felt when abstinence is protracted for a few hours only after the sense of hunger indicates the need of food. Every one knows that the deprivation of aliment, for a period varying according to circumstances, proves fatal. During the progress of starvation, the body loses rapidly in weight, the fat disappears, the muscles diminish in size, exhaustion progressively increases, the heat of the body is lowered, vomiting and diarrhœa not infrequently occur, the mental powers are weakened, listlessness and hebetude are sometimes followed by delirium and coma, and, according to Chossat, if the deprivation of aliment be complete, death takes place when one-fourth of the weight of the body at the time aliment was withheld has been lost. The mode of dying is a type of slow asthenia. It is worthy of note that, during the progress of starvation, hunger is not usually a prominent symptom. If felt for a time, it is apt to disappear, and it may be followed by a loathing of food.

Inanition is a pathological condition entering into all diseases which interfere with the ingestion or the assimilation of aliment. The phenomena of inanition in cases of these diseases, are combined with the symptoms belonging to the particular disease which exists. The inability of the system to support, resist, and overcome disease proceeds, in a greater or less degree, from this element. The immediate cause of death in many cases of disease proving fatal by slow asthenia, is inanition, that is to say, starvation. These are facts of great practical importance, and they are not sufficiently appreciated by many practitioners of medicine.

An important practical bearing of these facts relates to alimentation in the management of diseases. Until recently, for many years, not only was the importance of alimentation not fully recognized in medical practice, but the dietetic treatment of most diseases contributed to inanition. The writings of Graves led to the employment of alimentation in fevers. It is not less important in all other diseases which tend to destroy life by asthenia. Patients may be starved to death in other diseases as well as in fevers. As a practical rule, it is an object in any disease in which the danger lies in the direction of asthenia, to meet, as far as practicable by alimentary supplies, the wants of nutrition. Harm may arise from the ingestion of food beyond the powers of digestion, but no harm can arise from an undue assimilation of food; on the contrary, the greater the assimilation, the less the danger from inanition superadded to the disease. Let it be borne in mind that, in all diseases tending to destroy life by asthenia, there is danger from inanition, but never from hyper-nutrition. In the language of Chossat, "inanition is a cause of death which marches silently in front with every disease in which alimentation falls below the normal standard. It reaches its natural termination sometimes

sooner and sometimes later than the disease which it covertly accompanies, and it may supersede the disease of which at first it was merely an incidental element."

Alimentation is important in diseases not attended with immediate danger. In proportion as the assimilation of food can be made to approximate to the normal standard, the phenomena of inanition are forestalled, the vital powers are better enabled to tolerate and overcome the disease, the duration of the disease may be shortened, convalescence is hastened, and the recovery is more likely to be complete. As regards the selection of food and the modes of its preparation in different diseases, in addition to dietetic rules based on general experience, our knowledge of alimentary principles, etc., reliance may be placed upon the desires and tastes of the patient; but the absence of appetite is not to be a guide as regards alimentation. Loss of appetite is one of the symptoms of inanition. The wants of the system are not in disease, as in health, always expressed by hunger. The state of the mind, dependent on the morbid condition of the nervous system, the coatings on the tongue, etc., interfere with the desire for food and the sense of taste. The practitioner is to exercise his judgment and tact in securing, as far as practicable, the assimilation of an adequate amount of nutriment, either with or without the co-operation of desire and taste on the part of the patient, and it is often better to incur risk of exceeding, rather than falling below, the amount of food which the wants of the system require. It may be laid down as a principle applicable to the management of most acute diseases, that the assimilation of food to the fullest practicable extent is important; and it is a maxim of conservative medicine that, under all circumstances, a chronic affection is less likely to be prolonged, serious lesions of structure are less liable to take place, and a fatal termination is postponed, in proportion as the vital powers are maintained by a nutritious diet.[1]

Innutrition is not infrequently involved in the causation of diseases. The connection between scarcity of food and the prevalence of typhus has been repeatedly observed in epidemics in Ireland. The same connection in individual cases and families is observed frequently everywhere. Scorbutus is caused by a deficiency of certain alimentary principles, or the want of a sufficient variety in food. Insufficient nourishment, which is sometimes involuntary and sometimes voluntary, favors the development of phthisis in persons having the tuberculous diathesis. This cause may co-operate with other causes in giving rise to various diseases, whether epidemic or sporadic; and the ability of the system to bear up under disease is impaired in proportion as the powers of life are enfeebled by previous defective alimentation.

Want of success in the treatment of diseases in hospitals and often in private practice, especially among the poorer classes, is attributable, in no small measure, to the want of effective alimentation.

Gastralgia.

Gastralgia, called frequently gastrodynia, is a neuralgic affection characterized by pain, more or less intense, referred to the region of the stomach. Pain is a symptom of gastritis, carcinoma of the stomach, and gastric ulcer, it also enters into the clinical history of dyspepsia, especially the variety called acute dyspepsia, and a peculiar character of pain constitutes the dys-

[1] *Vide* Essays on Conservative Medicine, by the Author, American Journal of the Medical Sciences, January and October, 1863. *Vide*, also, essay on Alimentation in Disease, New York Med. Journal, 1867, and the work entitled Essays on Conservative Medicine and Kindred Topics.

peptic symptom called cardialgia or heartburn. But, considered as characterizing a distinct functional affection, the pain is not incidental to inflammation or any appreciable lesion, nor is it always, although frequently, associated with dyspeptic disorder; in short, gastralgia exists when pain and other circumstances denote an affection of the same pathological character as neuralgia in other situations.

Gastralgia is presented in practice in two forms: in one form a severe attack of pain occurs, and, if not relieved by remedies, it continues for several hours or even days. The pain is often excruciating, subduing the strongest resolution; the patient writhes and groans with intense suffering. A sense of constriction frequently accompanies the pain; vomiting may occur, but its occurrence is rare. Generally, tenderness over the epigastrium is wanting, and some relief may be afforded by pressure. The paroxysm is not attended with pyrexia, and the skin may be bathed in perspiration from the intensity of pain. These attacks are generally attributed to spasm or cramp, and the affection has been called colic of the stomach. It is difficult to say how much of the suffering is due to spasmodic contraction, and how much to neuralgic pain. Practically, it is not important to make this discrimination.

Such attacks in some persons are produced by certain ingesta. Strawberries, for example, have been known to prove in this way poisonous, and I have met with a patient who had always an attack after eating honey; he came under my observation when suffering from an attack thus produced. These, like other idiosyncrasies, are inexplicable. Attacks appear to be sometimes attributable to exposure to cold, and to fatigue from over-exertion.

This form of gastralgia is readily discriminated from acute gastritis. The pain may be much more intense than in cases of the latter disease. As a rule, the tenderness over the epigastrium which belongs to the history of gastritis, is wanting. Vomiting may be wanting, and, if present, is not as prominent a symptom as in gastritis. The absence of pyrexia is an important point in the exclusion of gastritis. The passage of gall-stones or hepatic colic offers many symptoms in common, and this discrimination is not at once readily made. The points involved in the differential diagnosis will be considered presently in treating of the passage of gall-stones.

This form of gastralgia is to be treated by opiates carried to the extent of procuring relief. A quarter or a half of a grain of a salt of morphia may be sprinkled on the tongue, and this dose repeated, if necessary, after the lapse of from half an hour to an hour, until the pain is relieved; or the same course may be pursued with other forms of opiate. If the opiate be rejected from the stomach, it may be given *per enema*. The hypodermic mode of administration is well suited to this affection, as to all affections in which it is desired to produce quickly and efficiently an anodyne effect. This plan of treatment is not to be deferred for the operation of a cathartic, or an emetic, even if the attack be attributable to dietetic cause. A sinapism and fomentations to the epigastrium are useful as auxiliary measures. An alcoholic stimulant may be added with advantage, if not contra-indicated by vomiting, especially if the pulse be feeble and the surface cold. Rest, regulated diet, and a mild cathartic or laxative, provided the bowels do not act spontaneously, will constitute the subsequent treatment.

Although the suffering is as great as in any other affection, there is little or no danger. It may be doubted whether this affection, alone, ever proves fatal; and the practitioner may count with confidence on procuring speedy relief by means of the plan of treatment just stated. The affection, therefore, is one of those which exemplify, in a striking manner, the resources of medicine.

The foregoing form of gastralgia may be distinguished as *acute*. In the

other form, the affection becomes *chronic*. The pain, in the latter, is either limited to paroxysms which recur more or less frequently, or it is habitual, with exacerbations at variable intervals. The pain varies much in different cases, as regards intensity, and also in different paroxysms or exacerbations in the same case. It may have so little intensity as to occasion only annoyance, or it may be so severe as to give rise to extreme suffering. The character of the pain is described by patients as burning, lancinating, or gnawing. Frequently the pain extends from the epigastrium in different directions, namely, to the back, into the chest, and, laterally, into the right and left hypochondrium.

With the affection, in some cases, are associated dyspeptic ailments, and in other cases there is no disorder of digestion. Paroxysms or exacerbations sometimes appear to be provoked by the ingestion of food, but, as a rule, relief of pain is felt after eating. The desire for food is oftener increased than diminished. Generally, tenderness over the epigastrium is wanting, and pressure frequently affords relief. The decubitus during the suffering from pain is sometimes upon the belly. Constipation exists much oftener than looseness of the bowels. Flatulent distension of the stomach or intestine is sometimes associated. The pulse preserves its normal frequency and the temperature of the body is not increased. Patients who have suffered from the malady for some time are apt to become melancholic and hypochondriacal. I have known it to be associated with a tendency to suicide.

Gastralgia rarely, if ever, occurs under the age of puberty, or in old age. It is generally considered that women, much more than men, are liable to it, but of 39 cases analyzed by Valleix, only 20 were females. It affects those of good constitution and the robust, as well as the feeble and delicate. Persons of sedentary habits are more likely to be affected than those engaged in active pursuits. Prolonged mental depression has been supposed to favor its occurrence. It appears in some cases to depend on the gouty diathesis. Like neuralgia in other situations, it may be an effect of malaria; and attacks of gastralgia may recur with the regularity of the paroxyms of intermittent fever. I have known gastralgia to take the place of the cold stage of the paroxysm, being followed by the hot and the sweating stage. Finally, causes which induce anæmia, or lead to debility, may be more or less involved in its production.

The diagnosis of the chronic form of gastralgia is to be based on certain distinctive characters, namely, the occurrence of pain either in paroxysms or marked exacerbations; the relief frequently afforded by pressure and the ingestion of food; the persistence of appetite in many cases; not infrequently, the absence of disorder of digestion, and the absence of pyrexia. These points in the history are involved especially in the discrimination of gastralgia from subacute or chronic gastritis. The diagnosis involves the exclusion of gastric ulcer and cancer. These affections are to be excluded by the absence of their diagnostic symptoms, irrespective of pain. In some cases of intercostal neuralgia, pain is referred to the epigastrium. This affection is excluded by the absence of its diagnostic criterion, namely, tenderness on pressure over three points—posteriorly, laterally, and anteriorly.[1]

Chronic gastralgia is apt to be persisting. Its duration, in different cases, is extremely variable. In this respect it resembles other neuralgic affections. It may continue for many months, and it sometimes persists for many years. As regards prognosis, the worst to be apprehended is the protractedness of the affection. It does not tend to destroy life either directly or by eventuating in some other more serious disease. It is not prudent for the practi-

[1] *Vide* page 191.

tioner to predict that the affection will end speedily, or within any definite period; yet, not infrequently, it does not continue. In certain cases it is one of the affections most rebellious to therapeutical measures, but in other cases it is readily amenable to treatment.

In the treatment of gastralgia, clinical experience has abundantly shown certain measures formerly in vogue to be not only ineffectual but prejudicial. This remark has reference to general and local bloodletting, emetics, mercurials, purgative remedies, and perhaps also vesication or other modes of active counter-irritation. Anodyne remedies are frequently called for to relieve pain. If the pain be severe, opium can hardly be dispensed with; but in this, as in other painful affections which are apt to be persisting, the liability to the formation of a habit of using opium is to be considered. Moreover, the use of opium, aside from the palliation of pain, is objectionable on account of its interference with the appetite and digestion, and, in this way, it may contribute to perpetuate the affection. Opium is, therefore, to be used with circumspection, and, when practicable, other palliative measures are to be substituted, such as belladonna, hyoscyamus, etc. Fomentations and embrocations containing opium, chloroform, aconite, etc., will sometimes succeed in affording relief. Cold applied to the epigastrium has been found effectual. Certain remedies appear, in some cases, to exert a curative influence. Bismuth is one of these. I have known large doses of this remedy to be promptly curative. Monneret advises it to be given to the extent of one, two, or three ounces daily. These enormous doses are not required. Whatever curative power the remedy has will be exerted in doses of from a scruple to a drachm three or four times daily. Alum has been recommended in doses of from ten to twenty grains three or four times daily. Strychnia and nux vomica have been found useful, especially if the affection be associated with the formation of gas. A quarter of a grain of the extract of nux vomica may be given three or four times daily. Other remedies which may be employed with a view to a curative effect are the nitrate of silver, the subcarbonate of iron (precipitated carbonate or sesqui-oxide) given in drachm doses, the iodide of potassium, and arsenic, as in other neuralgic affections. Another remedy is the purified oxide of manganese in doses of from five grains to half a drachm three times daily. Of curative remedies, in my experience, quinia in full doses is most likely to prove successful. The doses should be sufficient to produce cinchonism which should be steadily maintained for about two weeks. If, at the end of this time, a curative effect be not exerted, it is useless to continue the remedy longer. Although it often succeeds, it not infrequently fails. Salicin, a drachm or more given daily, is sometimes curative. In the hands of Leube, Beard and Rockwell, and others, electricity has proved efficacious. The constant current is the form to be employed.

Measures of treatment, other than the employment of direct curative remedies, are of importance. Change of habits from those of sedentary to active life, is of the first importance in certain cases. The moral influence of recreation, change of scene, etc., is often of more service than medicines. The diet should be nutritious. It should not be restricted. Alcoholic stimulants in moderation with meals may be advised for a time, exercising that reserve dictated by the danger of patients becoming addicted to their habitual use. Tonic remedies, in most cases, continued steadily for a long period, and varied from time to time, are advisable. The valerianate of zinc may be mentioned as a tonic remedy likely to prove useful. Preparations of iron are especially indicated if anæmia be present. Dyspeptic ailments, which may or may not be associated, are to receive appropriate treatment. In short, the object, aside from the employment of palliative and curative remedies, is to endeavor to place the digestive organs and the system in the best possible

condition, and, for this end, hygienic and medicinal measures are to be adapted to the circumstances peculiar to individual cases.

Passage of Gall-stones. Hepatic Colic.

The passage of biliary calculi along the cystic and common duct may give rise to symptoms resembling those of acute gastralgia. The discrimination, at once, is not always easy. Moreover, a paroxysm of pain from the passage of a gall-stone, or hepatic colic, is to be discriminated from affections other than gastralgia, namely, peritonitis, ordinary colic, colic with intestinal obstruction, acute gastritis, and the passage of calculi from the kidney to the bladder. Biliary calculi usually form in the gall-bladder, but they have been found in the hepatic duct and its branches within the liver. They vary in size from that of a pin's head to that of a hen's egg. They are frequently found in the gall-bladder after death, and sometimes in great number. A collection of several hundred is not uncommon. Bennett relates a case in which the number amounted to two thousand, and cases have been reported in which the number was still greater. They are usually of soft consistence, and of low specific gravity. They are sometimes white, but oftener either of a yellow, brown, or greenish color from the imbibition of bile. On section they are often found to consist of successive layers which differ in consistence and color. In general they are composed chiefly of cholesterin, but they frequently contain the salts of lime. Remaining within the gall-bladder, they may occasion no inconvenience; but, if many or large, they may give trouble by distending the gall-bladder, and they may lead to ulceration and perforation. If the perforation be into the peritoneal sac, peritonitis follows, and will be likely to prove fatal. If the distended gall-bladder become adherent to the abdominal walls, the perforation may lead to circumscribed abscess which opens externally, and numerous calculi may be discharged through the fistulous opening.[1] They are also sometimes discharged by an ulcerated opening into the intestinal canal. Gall-stones sometimes occasion a noise like that produced by the collision of nuts or marbles in a bag when shaken, if forcible pressure or strong percussion be made over the distended gall-bladder. But, in general, their existence is not suspected until, having entered the cystic or common duct, they occasion, by their passage toward the intestine, paroxysms of so-called hepatic or gall-stone colic. It is evident that the time occupied in the passage of a gall-stone, and the suffering, will depend, other things being equal, on its size and the irregularity of its shape.

The pain occasioned by the passage of a gall-stone is frequently abruptly developed without any obvious cause, but in some cases it is preceded by a sense of uneasiness referred to the right hypochondrium. In the majority of cases the attack occurs three or four hours after a meal. The suffering is often extreme, causing the patient to writhe and try a variety of positions with the hope of obtaining relief. The pain is referred to the epigastrium or the right hypochondrium. It may radiate thence throughout the abdomen, often extending into the chest, and to the right shoulder. Usually there is more or less tenderness over the seat of the pain, but in some cases pressure affords a certain measure of relief. Vomiting speedily occurs in the majority of cases, and is repeated more or less frequently during the continuance of the pain. The bowels are constipated. The pulse, as a rule, is not accelerated, and it may be retarded; not infrequently it becomes small and weak. The retardation of the pulse is sometimes notably great; I have

[1] For an account of reported cases, and also cases of cholecystotomy, *vide* article by Dr. G. W. H. Kemper, in Transactions of the Indiana State Medical Society, 1879.

known it to fall to 30 and 20 beats per minute. Pallor of the face and coldness of the surface are marked in some cases. Chilly sensations, with rigor, are not uncommon. These symptoms are sometimes so marked as to suggest the existence of malarial disease. The duration of the paroxysm is variable; it may last for a few moments only, or for many hours, depending, of course, on the period occupied by the passage of the stone either onward into the intestine or backward into the gall-bladder. At length, the pain and other symptoms suddenly cease, and nothing remains but more or less soreness and the fatigue occasioned by the suffering. If the paroxysm have been of considerable duration, the urine may show the presence of bile, and jaundice is frequently produced. These symptoms disappear after the paroxysm is ended. The dejections may show deficiency or absence of bile. The absorption of bile, and its absence in the stools, show that the gall-stone is impacted in the common, not the cystic, duct, and that its form and size are sufficient to cause obstruction more or less complete. Under these circumstances, the bile may accumulate within the gall-bladder and distend it so that it can be perceived by the touch below the lower margin of the liver. Finally, after the paroxysm is ended, one or more gall-stones may be discovered in the dejections if these be carefully examined. In some cases, however, careful examinations of the feces fail to show the presence of a calculus, or of calculi. The failure to discover them is not proof that an attack of hepatic colic has not been experienced, for the gall-stones, in these cases, after remaining for a time in the cystic duct, may have passed backward into the gall-bladder.

When one attack has been experienced, recurrences are to be expected, but, as regards the intervals, cases differ greatly. Successive attacks may occur after days, weeks, months, or years. Not infrequently a greater or less number of attacks are experienced in quick succession, several, perhaps, occurring in the same day, and for several days in succession. This is probably owing to the temporary dilatation of the cystic and common duct produced by the passage of calculi of considerable size, in consequence of which other stones within the gall-bladder more readily escape. The patient, under these circumstances, may be consoled by the reflection that the more frequent the passage of calculi, the less are the number remaining to give rise to subsequent attacks, provided, of course, they pass through the common duct into the duodenal cavity. The frequent repetition of attacks, if severe, may occasion considerable disturbance of the digestive system, and general prostration.

The differential diagnosis of the passage of gall-stones from acute gastralgia is to be based on the following points: The occurrence of pain, not excited by any obvious dietetic or other cause; the prominence of vomiting as a symptom; the presence, generally, of more or less tenderness; the existence of bile in the urine, and of icterus or an icterode hue of the conjunctiva and skin; retardation of the pulse; the persistence of pain, notwithstanding opiates are given in full doses; the sudden relief occurring irrespective of remedies; and, after the attack, the discovery of biliary calculi in the evacuations.

The examination of the evacuations for gall-stones not only serves to establish the diagnosis, but, on the appearance of the stone, or stones, may be predicated an opinion that the gall-bladder either does, or does not, contain calculi which have not escaped. If a single round or oval stone only be discovered, it is probable that this was a solitary calculus in the gall-bladder, and other attacks need not be expected; but if several stones be discovered, polyhedral in form, with smooth or polished facets, which may be plane, convex, or concave, it is highly probable that the gall-bladder contains others, and the patient cannot count on being exempt from repetitions of the parox-

ysms produced by their passage. The most effectual mode of examining for the presence of stones is to dilute the feces and strain through a sieve.

Acute peritonitis may be accompanied by pain resembling in intensity that of hepatic colic. But, in determining the existence of the latter, peritonitis is excluded by the absence of tenderness diffused over the abdomen, of rigidity of the abdominal walls, of tympanitic enlargement, of the notable acceleration of the pulse and pyrexia, together with the general prostration which belongs to the clinical history of peritoneal inflammation. Peritonitis, however, may proceed from perforation of the biliary canal, caused by the persistent impaction of a gall-stone. In cases of intestinal colic, the pain is more paroxysmal, with intervals of freedom from pain. Intussusception and internal strangulation of the intestine are to be excluded by the absence of a tumor caused by the accumulation of the intestinal contents at the point of obstruction, by the absence of obstruction, and of acceleration of the pulse, together with the greater gravity of the general symptoms in those affections. In acute gastritis, vomiting is a more prominent symptom than in hepatic colic, and the greater gravity of the affection is shown by the pulse and other general symptoms. In some cases of hepatic colic, the pain extends downward in the direction of the right ureter, so that the passage of a calculus along this duct may be suspected. The absence of certain symptoms belonging to the history of so-called renal colic, namely, retraction of the testicles, deficiency of the urine, hæmaturia, etc., will serve to exclude this affection. Knowledge of the occurrence of one or more prior attacks which have been ascertained to be due to the passage of gall-stones, will aid in determining the diagnosis. The age of the patient is of some account in the diagnosis. Gall-stones may form at any age, but they are most apt to form in middle or advanced life, and in females oftener than in males.

In the great majority of cases, gall-stones escaping from the gall-bladder find their way into the intestine, giving rise to no evil results beyond the pain, etc., which their passage occasions. But occasionally a stone becomes permanently impacted in the biliary canal, and, if situated in the common or hepatic duct, retention of bile ensues, giving rise to persisting jaundice and softening of the liver from the distension of the bile-ducts. Under these circumstances cirrhosis sometimes develops, ulceration and perforation of the duct are liable to take place, leading to peritonitis; or adhesive circumscribed peritonitis may have preceded the perforation, and this extending through the intestinal coats, the stone may be discharged into the intestine or through the abdominal walls. Obliteration of the canal of the common duct, as a result of inflammation and ulceration excited by the presence of the stone, sometimes occurs.

The rationale of the formation of gall-stones is not well understood. Probably the deposit in a solid form of certain of the constituents of bile takes place in consequence of the presence in the biliary passages or gall-bladder of mucus, collections of which are the nuclei for the formation of calculi. Hence gall-stones may be the result of inflammation of the gall-bladder or ducts. It has been conjectured that cholesterin may be deposited in consequence of the bile losing the faculty of holding this principle in solution from a diminution of the tauro-cholic acid. It is not improbable that an excess of the salts of lime or of bile pigment may lead to the production of nuclei.

The treatment of a paroxysm of hepatic colic consists of palliative measures. Opiates are called for in doses proportionate to the intensity of the pain, either administered by the mouth or rectum, or hypodermically. The degree of suffering, in some cases, is such that the inhalation of chloroform or ether is called for as a palliative measure. Warm anodyne fomentations may be applied to the seat of pain. The hot bath may aid in procuring

relief. The local application of cold by means of a bladder filled with pounded ice has been found to be useful as a palliative measure. Remedies to palliate vomiting may be indicated. Effervescing draughts and the hydrocyanic acid may be employed for this purpose. An alkaline remedy may be found useful, if, as is frequently the case, the matters vomited show notable acidity of the stomach. The foregoing palliative measures will alleviate the suffering, but it is not to be expected that they will procure complete relief.

Emetics and cathartics have been advocated under the notion that they aid in the passage of the stone. It is irrational to suppose that they have this effect, and clinical observation does not furnish evidence of their value. The passage of the stone is mainly due to the accumulation of bile behind it after it enters the common duct. Exciting the movements of the stomach and intestine by emetics and cathartics, if any effect be exerted, is as likely to retard as to favor the onward passage of the stone. Nothing, in fact, can be done by means of these or other remedies to expedite its passage. All that the physician can do is to palliate suffering until the stone is propelled into the intestinal canal, supporting the strength, if need be, by alcoholic stimulants. If, however, the distended gall-bladder form a tumor which is appreciable by the touch, an effort may be made, by pressure with the fingers, to propel the bile in the ducts, and thus aid in the removal of the obstruction.

It would be desirable, if possible, to effect the solution of gall-stones within the gall-bladder. The alkaline carbonates are given for this purpose. They should not be steadily continued for a long period, but their use intermitted from time to time. A treatment for this end is known in France as Durande's method, and consists in the administration of sulphuric ether and the spirits of turpentine (3 parts of the former to 2 parts of the latter). Buckler[1] has proposed the use of chloroform in view of the solvency of cholesterin in this liquid. He has reported a case in which an indurated tumor felt through the walls of the abdomen directly over the inferior margin of the liver disappeared in five days under the use of chloroform given in teaspoonful doses after each meal. It was concluded that the tumor was the gall-bladder distended with calculi; but there is room for doubt as to the correctness of this diagnosis. It seems hardly probable that any remedies can be introduced into the system so as to enter into the composition of the bile largely enough to dissolve the cholesterin of which mainly biliary calculi are composed.

The occurrence of gall-stones cannot be anticipated, but, being known, it is, of course, desirable to prevent the formation of others. It would seem that sedentary habits predispose to them. A change, in this respect, is therefore advisable. A simple, wholesome diet, and measures having reference to the general health, are rationally indicated. The "grape cure" has been recommended as preventive. Buckler suggests the hydrated succinate of the peroxide of iron in cases in which gall-stones are known to have been passed, the object being to prevent their further formation; this remedy, as he supposes, controlling the fatty or cholesteric diathesis.[2] The alkaline mineral waters of Carlsbad, Vichy, and Marienbad are held in much repute as preventing the formation of gall-stones. It is to be remarked that clinical experience is not to be relied upon as affording evidence of prevention, inasmuch as the success of preventive measures cannot be proven.

Gall-stones of sufficient size to occasion intestinal obstruction are sometimes lodged in the alimentary canal. These escape from the gall-bladder,

[1] American Journal of the Medical Sciences, July, 1867, p. 51.

[2] This remedy is given by Dr. Buckler as follows: Hydrated succinate of the peroxide of iron, ℥iss; water, f℥viss. A teaspoonful after each meal, continued for several months; and resumed at intervals afterward.

not through the biliary passages, but by ulceration, the walls of the gall-bladder becoming adherent to the duodenum, or some other portion of the intestine.

A patient who consulted me, having suffered much from the passage of gall-stones, at one time took, for a number of days, a pint or more of olive-oil daily, at the suggestion of some one who assured him that, in this way, he had gotten rid of a large number of stones without pain. The patient stated that, under the use of this remedy, he discharged from the bowels an immense number of small hard bodies which were supposed to be biliary calculi. These are composed of a concrete form of fatty matter like the bodies passed in some of the cases of fatty diarrhœa which have been reported. A case is quoted by Dunglison, in which olive-oil, taken abundantly for the relief of pains attributed to gall-stones, caused a discharge of fatty matter of a globular form, varying in size from that of a small pea to that of a moderate grape, of sufficient consistence to bear being cut with a knife like soft wax.[1]

Diarrhœa.

The term diarrhœa is used to denote morbid frequency of intestinal dejections which are, also, liquid or morbidly soft, and often otherwise altered in character. Diarrhœa is a symptom of inflammation of the large and the small intestine, and of certain structural lesions, such as those incident to tuberculosis of the intestine and to typhoid fever. It is a functional affection when it is not dependent on inflammation or any appreciable lesion of structure. It is an element of other functional affections, namely, sporadic cholera, dyspepsia, and certain cases of colic. As a functional affection, it may be either transient or chronic.

Writers have made several varieties of diarrhœa, based on diversities as regards the dejections. It is sufficient to enumerate the more important of these diversities without considering each as constituting a separate variety of the affection. The following answers all practical purposes:—

A diarrhœa is said to be *fecal*, *feculent*, *stercoraceous*, or *simple*, when the dejections consist of the feces not changed in character, but simply morbidly soft or liquid. This form of diarrhœa is represented by the operation of cathartics which increase the peristaltic movements and give rise to a certain amount of transudation. The dejections in this form of diarrhœa have the normal fecal odor. They are called *bilious* when, from their yellow or green color, bile is supposed to be present in larger quantity than usual. The green color which has been considered as characteristic of the action of mercury upon the liver, according to Thudicum is due to the presence of subsulphide of mercury.[2] Robin states that the microscope shows the coloring matter to be biliverdin.[3] Diarrhœa is *serous* or *watery*, when there is an abundant discharge of liquid, that is, when there is copious transudation or enterorrhœa. This is represented by the operation of hydragogue cathartics, such as elaterium, jalap, and the bitartrate of potassa. The dejections are called *lienteric* when they contain undigested aliment. This form of diarrhœa is met with especially in children. A diarrhœa is *mucous* or *dysenteric*, when mucus is apparent in the dejections. An abnormal amount of mucus may be secreted from irritation alone, without inflammation, but if the mucus

[3] Sur les Humeurs.

be abundant, it denotes an inflammatory condition. This form of diarrhœa is represented by the operation of drastic cathartics, such as croton oil. Finally, in a rare form, called *adipose* or *fatty diarrhœa*, free fat or oil, in more or less abundance, is found in the evacuations. This last form claims some distinct consideration.

In cases of adipose or fatty diarrhœa, the fat is generally liquid when passed, resembling melted butter or grease, having, when cold, the consistence of butter, beef tallow, or wax. In some cases it is passed in the form of globular concretions, of a waxy consistency, varying in size, which melt with heat and burn like tallow. The fat is often passed by itself, and is apt to be passed involuntarily in a small quantity at a time. When passed with the feces, it separates and collects on the surface. It has usually an extremely offensive odor. The quantity passed *per diem*, in cases which have been reported, varies from two or three ounces to half a pound or more.

Assuming all the fat passed from the bowels to have been ingested as fat, the rationale involves simply the non-digestion of this alimentary substance. But in some reported cases it is stated that the quantity of fat passed was not affected by the amount of fatty food. In a case reported by Wells, the patient abstained for several weeks from fatty food, and, as far as convenient, from articles convertible into fat, without any diminution in the quantity of fat passed, nor was the latter affected by indulging freely in fatty food.[1] In two cases reported by Bright, no change was produced by excluding, as far as possible, from the diet fatty articles. That the non-digestion of fat is, in a great measure, involved in the pathological explanation, is, however, not to be doubted. Physiological researches have shown that the pancreatic secretion, together with the bile and intestinal juice, effects the digestion of fat, and hence we are to look to the sources of these fluids in tracing the causation of fatty diarrhœa. It is an interesting fact that Bright, long before the discovery of the particular function of the pancreas by Bernard, was led, by an analysis of three cases which came under his observation, to consider fatty diarrhœa as a symptom of disease of the pancreas. In these three cases, the only lesions found after death which were common to all, were of the pancreas, duodenum, and liver. He excluded the lesions in the two latter situations because they occur in these organs so often without fatty diarrhœa, but he admits that disease of the pancreas is not always accompanied by this symptom.[2] The pancreas has been found diseased in a large majority of the reported fatal cases in which this organ was examined after death. Of twenty-five cases tabulated by Griscom,[3] in ten the bodies were examined after death; of these ten cases, in eight the pancreas was diseased, and in the remaining two cases the absence of disease of the pancreas is not stated. Yet fatty diarrhœa occurs in only a small proportion of the cases of disease of the pancreas. Thus, it was observed in only three of thirty-seven cases of cancer affecting this organ tabulated by Da Costa.[4] Hence, it is to be inferred that, in connection with disease of the pancreas, lesions or morbid conditions affecting liquids, other than the pancreatic secretion, concerned in the digestion of fat, are generally involved. Of the fatal cases among those tabulated by Griscom in which the morbid appearances were observed, the liver in several

was either diseased or its ducts engorged; but in some of the cases this organ appeared to be healthy. The fact of complete recovery taking place in a certain proportion of cases, goes to show that the non-digestion of fat may occur as a functional disorder.

A larger number of cases than are as yet available are required in order to establish the clinical history, as well as the causation and pathological relations, of this form of diarrhœa. Jaundice was noted in several (six) of Griscom's cases. Diabetes mellitus co-existed in two cases. Hemorrhage from the bowels, vomiting, pains in the abdomen sometimes resembling those caused by the passage of gall-stones, are among the symptoms noted in these cases. The duration of the affection varies much in different cases. In one case it had existed at frequent intervals for six years; in another case for two years; and in one case it disappeared after a few weeks. It is evident that the prognosis is to be based on circumstances other than the discharge of fat, namely, enlargement of the pancreas and liver, persisting jaundice, progressive emaciation, etc.; in other words, the danger depends on the lesions or morbid conditions on which the discharge of fat may be dependent, or with which it is associated. Of the 25 cases collected by Griscom, 14 died, 8 recovered, and in 3 the termination was not noted.

The treatment must have reference more to the circumstances connected with the fatty diarrhœa than to the latter. With our present knowledge, palliative measures according to the symptoms in individuals cases, together with measures to improve digestion and invigorate the general health, comprise the treatment. In one of Griscom's cases recovery took place under the use of olive oil in large quantity; and Watson states that a case was successfully treated by Elliotson in the same way. In a case observed by Griscom at the New York Hospital, the discharge of fat invariably ceased whenever the patient took from six to eight ounces of whiskey *per diem*. In the case reported by Wells, the patient having had a daily discharge of three gills of fat for two years or more, recovered in a few weeks after giving up the occupation of a carpenter and adopting the life of a farmer.

Exclusive of the form just considered, diarrhœa involves different pathological elements, namely, increased peristaltic movements, increased transudation, increased secretion from the mucous follicles, and perhaps, increased flow of bile. If the diarrhœa be purely functional, of course there is no inflammation of the mucous membrane. Practically, it is not always easy to determine whether diarrhœa be purely functional or dependent on subacute inflammation. But, with reference to the treatment, to determine this point is not of great importance. It is not improbable that, of the cases considered as functional, in a certain proportion there is a slight grade of inflammation, such as exists in coryza or a mild bronchitis. In making the diagnosis, acute inflammation is to be excluded by the absence of diagnostic symptoms, namely, pain, tenderness, febrile movement, anorexia. So, also, lesions of the mucous membrane are to be excluded. In cases of chronic diarrhœa this is not always easy. Lesions are to be suspected if the diarrhœa follow an attack of dysentery or enteritis, if it persist in spite of judicious management, if blood be sometimes present in the dejections, and if tubercles exist in the lungs. In the latter case, tuberculosis of the intestine is to be suspected, and, on the other hand, persistent or frequently recurring diarrhœa, conjoined with cough, be the latter never so slight, should excite suspicion of pulmonary phthisis.

Transient diarrhœa due to arrested or defective intestinal digestion, is of frequent occurrence. With the diarrhœa which follows over-indulgence at the table, or the ingestion of certain articles of food, every one is practically familiar. This is the *diarrhœa crapulosa* of the old writers. It may proceed from excesses in quantity, or from particular kinds of food, the indigestibility

of the latter, perhaps, showing an idiosyncrasy of the person affected; thus, ices, salads, shell-fish, etc., in some persons always, and occasionally in all, give rise to transient diarrhœa. The undigested aliment, passing into the large intestine, having undergone chemical changes which the processes of digestion in health prevent, produces irritation and acts like a cathartic remedy. Frequently the diarrhœa is preceded and accompanied by griping pains, and it may be, under these circumstances, an element of another functional affection, namely, colic. These attacks of diarrhœa cease spontaneously, as a rule, after the expulsion of the undigested matter, and they are rarely considered of sufficient importance to require medical advice.

An arrest of intestinal digestion may take place from causes other than errors of diet, and give rise to diarrhœa. A strong mental emotion may have this effect. I was present at an operation for hernia when the surgeon, from the mental anxiety incident to his sense of responsibility, was obliged to relinquish the scalpel and precipitately retire to evacuate the bowels. A gentleman in business receiving, suddenly, unexpected information which led him to know that he was a bankrupt, was immediately seized with diarrhœa. In like manner diarrhœa may arise from an arrest of digestion from an exposure to cold or from over-exertion. In these cases the mechanism is the same as when the diarrhœa depends on dietetic errors, the undigested aliment in the large intestine acting like a cathartic.

Diarrhœa, not transient, but continuing more or less, perhaps becoming chronic or recurring at short intervals, also proceeds, in a large proportion of cases, from indigestion. Habitual or frequent indigestion, especially intestinal indigestion, leads to diarrhœa in the same way as when it is transient, namely, the undigested aliment undergoes chemical changes and causes irritation of the large intestine. The dejections, as in transient diarrhœa, may be feculent, bilious, mucous, lienteric, or, more rarely, serous. The diarrhœa in these cases is, in fact, an element or symptom of dyspepsia, but not infrequently, the disorder of digestion being confined mainly to the small intestine, dyspeptic ailments, aside from the diarrhœa, are not marked. The indigestion thus giving rise to diarrhœa may be produced and kept up by various causes independent of excess or errors of diet; in fact, the causes are those of dyspepsia, mental anxiety often playing an important part in the causation.

It has been customary to attribute diarrhœa, in certain cases, to an excess or a vitiated quality of bile. This causation is inferred when the dejections are notably bilious. This view is not improbable, although not based on positive knowledge. The bile may not be reabsorbed from the alimentary canal, as in health, and hence accumulates in excess, without a morbid increase in the secretion; it may be secreted in undue quantity, or it may have a morbidly irritating property.

Diarrhœa is most apt to occur during the summer season. This may be, in part, explained by the larger proportion of fruit and vegetables in the ingesta during this season, and by the effect of heat in weakening digestion. It may also in part be due to a more abundant secretion, or to a lessened absorption, of bile. It is a much more frequent affection in tropical than in cold or temperate climates. It is apt to occur in travelling, especially in the summer season. Its occurrence is generally attributed to the drinking-water, but a more rational explanation is to refer it to indigestion caused by dietetic errors, over-exertion, and disturbance of the regular habits of life. Children are far more subject to diarrhœa than adults, especially during dentition, and in children the dejections are often manifestly lienteric, showing its dependence on indigestion. It is the most prominent feature of the affection known as *cholera infantum*, or, popularly, in this country, *summer complaint*. Among soldiers, especially in campaigns during the summer season, or in

warm climates, diarrhœa is extremely common, attributable to irregular habits as regards diet, conjoined with the exposure and fatigue incident to active service. Diarrhœa occurs in persons exhausted from the want of food or other deprivations, and in females enfeebled and anæmic from protracted lactation, due in these cases to intestinal indigestion. The same explanation, probably, applies to the diarrhœa which occurs at a late period in cases of pulmonary phthisis and other chronic affections, when not dependent on intestinal lesions. Under these circumstances it has been called *colliquative diarrhœa.*

The accumulation of urinary principles in the blood, as a consequence of renal disease, occasions diarrhœa. The diarrhœa and vomiting which occur under these circumstances appear to be for the purpose of eliminating vicariously urea, and are, therefore, conservative. They occur when the kidneys are removed in inferior animals, and, as shown by the experiments of Bernard and Barriswill, the liquid transudation into the alimentary canal contains either urea or the carbonate of ammonia. The dejections in uræmic diarrhœa are serous or watery.

Another pathological condition occasionally giving rise to diarrhœa, is congestion of the portal vessels when the circulation in this portion of the vascular system is obstructed by hepatic disease. It thus is a symptom in some cases of cirrhosis of the liver, and it sometimes appears to limit the dropsical effusion into the peritoneal sac, which belongs to the history of that disease. The diarrhœa, under these circumstances, is serous, transudation taking place from the pressure of the blood within the congested veins.

Crapulous diarrhœa, or transient diarrhœa due to indigestion, in general calls for little or no treatment. If the contents of the large intestine be not spontaneously expelled, an evacuant remedy may be given. A saline purgative is best adapted to this end. The propriety of this measure is to be determined by ascertaining the quantity and character of the dejections which have occurred. If these have been abundant and feculent, a cathartic is not required. If, after the bowels have been freely evacuated, diarrhœa, pain, or uneasiness continue, the irritation may be quieted by a mild anodyne, for example, a drachm or two of the camphorated tincture of opium, for an adult, in chalk mixture, a grain of opium, a sixth or a quarter of a grain of a salt of morphia in mint water, or five grains of Dover's powder combined with two or three grains of aromatic powder. The remedy chosen is to be repeated after six or eight hours, if required. The diet for a day or two should be simple and somewhat restricted. Subsequently a laxative may be required if the bowels do not act spontaneously. The treatment of cases of diarrhœa tending to continuance or frequently recurring and dependent on indigestion, embraces, in the first place, remedies to relieve the irritation of the large intestine. Opium in some form may be used for this purpose, but only temporarily, because its continued use tends still more to impair digestion. A mild purgative may often be prescribed with advantage, for frequent and loose dejections are not incompatible with retention of hardened feces, in fact, with constipation. The subcarbonate or the subnitrate of bismuth is an excellent remedy to relieve intestinal irritation. It is often effective, and is not open to the objections of opium. It should be given in doses of from a scruple to half a drachm to adult patients. If not alone effective, a small quantity of a salt of morphia may be added to it. Of a variety of remedies tried in cases of chronic diarrhœa among soldiers returning from the campaigns in Virginia in the summers of 1862 and 1863, bismuth, in my hands, proved the most effective, and this, I believe, was the result of the experience of others. Opiates are sometimes most effective, and least objectionable, when given *per enema.*

Pepsin or the rennet-wine is sometimes useful temporarily as a means of artificial digestion, given as already recommended in cases of dyspepsia.

This part of the treatment, however, is merely palliative. The curative treatment embraces regulation of diet and measures to render digestion complete. The diet, in quantity and quality, should be adapted to the digestive powers. Chickens, eggs, and tender meats plainly cooked, are most likely to be digested, but in some cases a milk and farinaceous diet is found to be preferable. Experience in individual cases is to be the guide. Crude vegetables are to be interdicted, but ripe fruits, in moderation, may frequently be taken without inconvenience and with advantage. A moderate quantity of food, taken at short intervals, is generally advisable, rather than a full meal once or twice daily. A sea-voyage, a visit or removal from the city to the country, or the change of a warm, variable, humid, relaxing climate for an atmosphere cool, uniform, dry, and bracing, will be likely to prove highly beneficial, if not curative, in cases which resist dietetic and medicinal treatment. The efficacy of these measures is strikingly illustrated in cases of the so-called summer-complaint of children.

The remedies, other than those merely palliative, which are useful in the cases of diarrhœa under consideration, belong among the tonics and astringents; the latter may be both palliative and curative. Of the various vegetable astringents, krameria, hæmatoxylon, kino, catechu, and rubus villosus are eligible articles. The tannic acid, if well borne by the stomach, is sometimes efficient. As purely tonic remedies, quinia or the non-officinal preparations of Calisaya bark, so much in vogue, and other bitter infusions, are often useful. Salicin, in doses of ten grains three times daily, is an excellent tonic remedy. Preparations of iron are especially useful when the patient is anæmic, as in cases of diarrhœa occurring in females during lactation. The tincture of the chloride of iron is one of the best of the chalybeates. The persulphate or pernitrate of iron is sometimes efficacious as an astringent, as well as a tonic, remedy. Of mineral tonics and astringents, the acetate of lead, nitrate of silver, and the sulphate of copper have been found useful. The subcarbonate or the subnitrate of bismuth is of great value in chronic diarrhœa, not only as a palliative but as a curative remedy, given in large doses, namely, from a scruple to a drachm, three or four times daily, sometimes in combination with small doses of a salt of morphia, as recommended above, in connection with palliative measures of treatment. The mineral acids are efficacious in some cases. The preparation known as Hope's mixture has been much in use. This mixture is composed of four drops of nitric acid and from forty to sixty drops of laudanum in four ounces of camphor water, a tablespoonful to be taken every two, three, or four hours. In rebellious cases of chronic diarrhœa, the numerous remedies which have been named are to be given in succession, and in various combinations. The curative and palliative remedies are to be combined to meet the indications in individual cases.

Diarrhœa dependent on uræmia, and on cirrhosis of the liver, does not admit of curative treatment, and, being conservative, is only to be kept within certain limits by palliative remedies.

Enterorrhagia.

Hemorrhage into the intestinal canal is properly called Enterorrhagia. The term *melæna* has been used to denote dark-colored or black dejections consisting of blood which has passed from the stomach into the intestinal canal. Partial digestion of the blood, or the action upon it of the gastric and intestinal secretions, renders it tarry or pitch-like in appearance, and generally very offensive to the smell. Dejections of this character are apt

to follow gastrorrhagia. The term melæna has been also applied to cases of gastrorrhagia in which the blood vomited presents a similar appearance. Moreover, the term has been loosely applied to denote dark-colored or black evacuations, not consisting of blood. The term is one of those which it is desirable should become obsolete. Cases in which blood evacuated from the bowels comes from the stomach, or from any of the abdominal viscera other than the intestinal canal, are not cases of enterorrhagia. Nor are cases of hemorrhoidal or other hemorrhages occurring near the anus, properly embraced under this head. The source of the hemorrhage must be the mucous membrane between the stomach and rectum. The tarry or pitch-like appearance of blood in the stools is evidence of its gastric source. But this appearance is not positive proof that the matter evacuated is blood. It is probably blood if the stools have been preceded by the vomiting of blood, but in some cases of gastrorrhagia vomiting does not take place, all the blood passing into the intestinal canal. In doubtful cases, dilution in water of some of the matter evacuated, renders the appearance of blood more evident, or recourse may be had to the microscope or to the spectroscope. When the source of hemorrhage is the rectum, the blood is fresh in appearance, and is passed alone, in greater or less abundance, either after a fecal evacuation, or with straining efforts to procure a stool. Examination with the eye or touch will show the existence generally of hæmorrhoids, but, in some cases, other local affections, such as ulcers, carcinoma, a polypus, or intussusception.

In cases of enterorrhagia, the hemorrhage takes place in different situations along the tract of the small and large intestine. The blood is less changed in appearance the nearer the rectum its source, and the more quickly it is evacuated. If the hemorrhage be at the upper part of the intestinal tube, and the blood pass slowly along the tube, it becomes dark or blackish, its appearance resembling that of the melænic stools in cases of gastrorrhagia, and there may be a similar difficulty in determining whether the appearance be due to the presence of blood. The quantity of blood passed in different cases of enterorrhagia varies. It is frequently large, amounting, in some cases, to several pints and even quarts. Evacuations may consist wholly of blood, or the blood may be mixed with fecal matter. The blood may be entirely liquid, or the evacuations may contain clots in more or less abundance.

Intestinal, like gastric, hemorrhage has rarely any claim to be regarded as an individual affection. Like gastric hemorrhage, it is incidental to a variety of morbid conditions. It is an important occasional event in typhoid fever, and will be referred to in treating of that disease. It enters into the characteristic dejections of dysentery. It is one of the symptoms of embolism of the superior mesenteric artery. It occurs in cases of carcinoma of the bowels. It is a rare occurrence in tuberculous ulceration of the small or large intestine. It belongs to the natural history of scorbutus, purpura hemorrhagica, and yellow fever. Like gastric hemorrhage, it may be vicarious of menstruation. It is not an uncommon effect of the portal congestion occasioned by cirrhosis of the liver. It occurs, however, when not connected with these or any other discoverable morbid conditions. I have met with several examples of enterorrhagia not connected with any of the several causative conditions which exist in the larger proportion of cases. While, therefore, the chances are that some of these conditions exist, the occurrence of hemorrhage is not proof of the existence of any of them. Symptoms attributable to the loss of blood, and marked in proportion to the amount of hemorrhage, are debility, pallor, feebleness of the pulse, perspiration, sense of faintness, etc. The loss of blood may be sufficiently great and rapid to occasion sudden death, but this is rare. The repetitions of the hemorrhage may lead to a degree of exhaustion and anæmia from which recovery is difficult, and a fatal result may take

place by slow asthenia. In general, however, if the hemorrhage be not connected with morbid conditions which involve danger, the prognosis is favorable. Hemorrhage sufficient to occasion fatal syncope may take place and no blood be discharged by stool. In such a case, the diagnosis of enterorrhagia is impracticable.
